J. D. Holmes prepared needle-like crystals of a form of **ammonium octochlorotrimercuriate**, $3\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$, with 7 per cent. of combined water, which it loses when dried at 100° . P. A. Meerburg has shown that the monohydrated salt, $2\text{NH}_4\text{Cl} \cdot 3\text{HgCl}_2 \cdot \text{H}_2\text{O}$, and not the anhydrous salt, is formed at 30° in aq. soln. with between 13.90 and 56.83 per cent. respectively of ammonium and mercuric chlorides and between 9.23 and 58.55 per cent. respectively of the same two salts. A soln. with 14.14 and 56.98 per cent. respectively of ammonium and mercuric chlorides gives a mixture of the 1.1.1 and the 3.2.1 salts; and a soln. with 9.20 and 58.65 per cent. respectively of the same two salts gives a mixture of the 3.2.1 and the 9.2.0 salts. D. Strömholm made this salt by evaporating a hydrochloric acid soln. with three mols of mercuric chloride to one of ammonium chloride. The soln. is cooled when crystallization begins, and the crystals are dried by press. They lose a mol of water when dried in a desiccator or at 60° . J. D. Holmes also reported a tetrahydrated salt, $3\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$, in needle-like crystals by evaporating a soln. of the component salts with a great excess of hydrochloric acid—however this may be, the salt does not exist in aq. soln. at 30° .

J. D. Holmes also obtained triclinic crystals of **ammonium eicosichloro-enneamercuriate**, $9\text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$, that is, $(\text{NH}_4)_2\text{Hg}_9\text{Cl}_{20}$, by cooling a hot aq. soln. of one part of ammonium chloride and 25 parts of mercuric chloride acidified with hydrochloric acid. P. A. Meerburg found that the salt is formed in soln. at 30° with between 8.76 and 51.83 per cent. respectively of ammonium and mercuric chlorides, and 5.06 and 32.90 per cent. respectively of the same two salts. A soln. with 9.20 and 58.65 per cent. respectively of ammonium and mercuric chlorides gives a mixture of the 3.2.1 and 9.2.0 salts, and a soln. with 3.62 and 29.65 per cent.

respectively of the same two salts, a mixture of the 9.2.0 and 1.0.0 salts. According to J. D. Holmes, the sp. gr. of the salt is 3.06. The presence of free hydrochloric acid seems to retard the decomposition of this salt by water. When potassium hydroxide is added to the soln. a yellow precipitate is obtained which gives no ammonia gas even when boiled; the soln. gives a yellow precipitate with an excess of platinous chloride. P. C. Ray reported the formation of white crystals of **ammonium pentachloro-dimercuriate**, $2\text{HgCl}_2 \cdot \text{NH}_4\text{Cl}$, *i.e.* $\text{NH}_4\text{Hg}_2\text{Cl}_5$, by evaporating a soln. of dimercuriammonium nitrite, $\text{NH}_4\text{NO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, in warm dil. hydrochloric acid. The salt fuses and sublimes at a gentle heat, and is very soluble in water. D. Strömholm also reported the formation of rhombohedral crystals of **ammonium henicosichloropentamercuriate**, $5\text{HgCl}_2 \cdot \text{NH}_4\text{Cl}$, or $\text{NH}_4\text{Hg}_5\text{Cl}_{21}$, by a process analogous with that employed by J. D. Holmes for the 9.2.0 salt, and although H. L. Wells suggested that J. D. Holmes's 9 : 2 : 0 salt is really the 5 : 1 : 0 salt, P. A. Meerburg's work shows that the converse is the more probable, and D. Strömholm's, that the 5 : 1 : 0 salt is really the 9 : 2 : 0 salt. As indicated by T. Curtius and F. Schrader,⁴ hydrazine hydrochloride, like ammonium chloride, forms double salts with mercuric chloride. K. A. Hofmann and E. C. Marburg obtained crystals of **hydrazine trichloromercuriate**, $(\text{N}_2\text{H}_5)\text{HgCl}_3$, *i.e.* $\text{HgCl}_2 \cdot \text{N}_2\text{H}_5\text{Cl}$, melting at 157° , by the action of a soln. of chlorine in carbon tetrachloride on a soln. of mercurous hydrazinochloride, $2\text{HgCl} \cdot \text{N}_2\text{H}_4$, in the same solvent, and by re-crystallization from boiling alcohol. They also made it from the component salts with the mercuric chloride in excess. K. A. Hofmann and E. C. Marburg made **dihydrazine tetrachloromercuriate**, $(\text{N}_2\text{H}_5)_2\text{HgCl}_4$, *i.e.* $\text{HgCl}_2 \cdot 2\text{N}_2\text{H}_5\text{Cl}$, by evaporating to dryness an aq. soln. of 2.1 grms. of $\text{N}_2\text{H}_4 \cdot 2\text{HCl}$ and 3 grms. of mercuric chloride, acidified with hydrochloric acid; the excess of mercuric chloride was extracted from the powdered mass by cold absolute alcohol. It dissolves in hot alcohol, and the soln. crystallizes on cooling. The same salt is formed by the spontaneous evaporation of a soln. of the component salts in the proportion $\text{N}_2\text{H}_4 \cdot 2\text{HCl} : \text{HgCl}_2 = 2 : 1$. M. Adams reported **hydroxylamine trichlorodimercuriate**, $(\text{NH}_3\text{OH})\text{HgCl}_3$, *i.e.* $\text{HgCl}_2 \cdot \text{NH}_2\text{OH} \cdot \text{HCl}$; and **decahydroxylamine enneachlorodimercuriate**, $2\text{HgCl}_2 \cdot 5(\text{NH}_2\text{OH})_2\text{HCl}$, to be formed from soln. of the component salts. The latter is formed at a low temp., -10° .

W. Herz and W. Paul⁵ found that at 25° soln. containing 0.4.14, 17.38, and 35.27 milligram-mols of lithium chloride in 10 c.c. of water dissolved respectively 2.65, 3.51, 16.78, and 30.62 milligram-mols of mercuric chloride, and that the ratio for the more conc. soln. approximated to that required for $\text{LiCl} \cdot \text{HgCl}_2$. In 1829, P. A. von Bonsdorff claimed to have prepared needle-like crystals of a deliquescent double salt of lithium and mercuric chlorides; and, in 1893, E. C. Linebarger inferred the existence of **lithium trichloromercuriate**, LiHgCl_3 , *i.e.* $\text{HgCl}_2 \cdot \text{LiCl}$, in acetoacetic ether soln., because of the solubility of lithium chloride in soln. of mercuric chloride in this solvent:

	0°	10°	20°	30°	40°
Mols HgCl_2 per litre	8.2	0.9	6.3	0.6	6.4
Mols LiCl per litre	8.5	1.0	6.5	0.9	6.8

According to R. Varet, the heat of formation of this salt in soln. at 17° is 0.9 Cal. F. Calzolari and U. Tagliavini obtained lithium mercuric chloride, or lithium chloromercuriate, $\text{LiCl} \cdot \text{HgCl}_2$, which could not be crystallized, but complexes with hexamethylenetetramine were readily formed. P. Harth made **lithium tetrachloromercuriate**, Li_2HgCl_4 , *i.e.* $\text{HgCl}_2 \cdot 2\text{LiCl}$, by adding mercuric chloride to a sat. soln. of lithium chloride so long as any is dissolved. Needle-like crystals of the salt in question are deposited when the soln. is evaporated in vacuo. The salt decomposes when dried in vacuo; it is very hygroscopic; very soluble in water; and, according to R. Varet, has a heat of formation, in soln. at 17° , of 0.8 Cal.

J. Davy⁶ noted a soln. of sodium chloride dissolves a far greater proportion of mercuric chloride than is dissolved by water alone; and that rhomboidal

crystals of a double salt are obtained by cooling to 15° a warm soln. of 7 parts of sodium chloride and 35 parts of mercuric chloride in 20 parts of water. K. Voit obtained not the double salt $2\text{NaCl} \cdot \text{HgCl}_2$, but crystals of mercuric chloride. W. Herz and W. Paul measured the solubility of mercuric chloride in soln. of different proportions of sodium chloride at 25° , and found soln. containing 0, 2.12, 11.53, 19.41, and 31.62 milligram-mols of sodium chloride in 10 c.c. of water dissolve respectively 2.65, 3.72, 11.92, and 34.34 milligram-mols of mercuric chloride; in the more conc. soln., the ratio $\text{NaCl} : \text{HgCl}_2$ approximates to that required for the formation of the salt $\text{NaCl} : \text{HgCl}_2$. J. Davy found that warm soln. take up much more of these salts and, on cooling, deposit the same. J. Müller showed that a soln. with at least 10 times as much sodium as potassium chloride does not give some of the reactions characteristic of mercuric chloride—for instance, it does not coagulate albumen. J. von Liebig prepared needle-like crystals of what were regarded as **sodium tetrachloromercuriate**, $2\text{NaCl} \cdot \text{HgCl}_2$, or Na_2HgCl_4 , by precipitation from mixed soln. of the component salts. K. Voit also reported the formation of crystals of the same salt, but there is some doubt about its existence. A. Benrath inferred the existence of the complex salt Na_2HgCl_4 in aq. soln. from the lowering of the f.p. and the raising of the b.p.; and M. le Blanc and A. A. Noyes also from the electrical conductivities of these soln.

In a soln. of two salts *A* and *B* with a common ion present in excess only one sat. soln. is possible provided the salts do not form a double salt with one another.⁷ If the two salts do form a double salt *AB*, two sat. soln. will be possible, (1) when *A* and *AB* are present as solids, and (2) when *AB* and *B* are present. The single salts alone or a double salt alone can exist in contact with a series of sat. soln. containing *A* and *B*. Consequently, when *two* separate salts are present in the residue, the relative composition of the residue will change as the relative composition of the soln. changes, but the composition of the sat. soln. will remain constant; and when one salt—simple or double—is alone present in the residue, the composition of the residue will remain fixed, while the composition of the sat. soln. will vary. Consequently, if the composition of the residue varies in different determinations while that of the soln. remains constant, two salts are present in the system; while if the composition of the soln. varies while that of the residue remains constant, only one salt—single or double—is present in the system. In applying the method to practice, weighed quantities of the two salts *A* and *B* are placed in test-tubes containing a definite amount of solvent. The quantity of salts and solvent are so regulated that there is always an undissolved residue at the temp. of the experiment. The relative amounts of each salt are varied systematically in different test-tubes. The composition of the soln. can be determined by analysis, and that of the residue calculated provided the solids are anhydrous; when the salts contain water of crystallization the residue must also be analyzed.

The results obtained by H. W. Foote and L. H. Levy⁸ for soln. of sodium and mercuric chlorides at 25° , when the solubility of the former is 36.50 per cent., are as follows:

Per cent. NaCl soln.	18.66	18.71	18.87	14.97	14.03	13.17	12.97	13.15
NaCl in residue	83.64	78.02	28.75	16.38	16.36	15.96	11.80	9.17
Solid phase	$\text{NaCl} + \text{NaHgCl}_3 \cdot 2\text{H}_2\text{O}$			$\text{NaHgCl}_3 \cdot 2\text{H}_2\text{O}$			$\text{NaHgCl}_3 \cdot 2\text{H}_2\text{O} + \text{HgCl}_2$	

The results are plotted in Fig. 16. The vertical lines—soln. variable, residue constant—represent soln. with the solid phase of constant composition in aq. soln. at 25° ; the horizontal lines—soln. constant, residue variable—represent mixtures of salts. From this result it appears as if the only double salt formed at 25° is **dihydrated sodium trichloromercuriate**, $\text{NaCl} \cdot \text{HgCl}_2 \cdot 2\text{H}_2\text{O}$ or $\text{NaHgCl}_3 \cdot 2\text{H}_2\text{O}$; and similar results were observed at 10.3° . Had the compound $2\text{NaCl} \cdot \text{HgCl}_2$ or Na_2HgCl_4 been formed, the first three solubilities in the table would have been different. The similarity in the solubilities, and the variability in the composition of the

residues, show that a mixture of these two salts is involved. P. A. von Bonsdorff prepared sodium trichloromercuriate in 1829 by shaking a sat. soln. of sodium chloride

FIG. 16.—Solubility of Mixed Solutions of Sodium and Mercuric Chlorides.

with powdered mercuric chloride until the system was in equilibrium. Crystals of this double salt were obtained by C. Tournoux, by the spontaneous evaporation of the filtered soln. R. Schindler, and K. Voit likewise prepared needle-like crystals of this salt in an analogous manner. The earlier investigators supposed the salt to have the composition $\text{NaHgCl}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$. The salt melts at 100° in its own water of

crystallization, part of which evaporates with the loss of a little mercuric chloride; when heated more strongly, the soln. boils, mercuric chloride and water are driven off, and sodium chloride remains. Water dissolves 75 per cent. of the salt at 15° , and it can be crystallized unchanged from the aq. soln. J. L. Lassaigne found that ether extracts the salt from its aq. soln. Alcohol dissolves the salt copiously. The general reactions of the salt resemble those of mercuric chloride. E. C. Linebarger found at 0° , a soln. of 4.4, 12.0, and 22.0 mols of mercuric chloride in acetone dissolved respectively 4.4, 11.2, and 22.9 mols of sodium chloride in agreement with the existence of NaHgCl_3 in these soln.; analogous results were obtained at 5° and 10° . H. W. Foote says that in alcoholic soln. of mercuric and sodium chlorides no double salt is formed in the absence of water. E. C. Linebarger found also that the double salt is not formed in benzene soln., but in acetone soln. $\text{NaCl} \cdot \text{HgCl}_2$ is formed, and K. Voit says the anhydrous salt is made when the dihydrated salt is evaporated over sulphuric acid. According to R. Varet, the heat of formation from its constituents in soln. at 17° is $(\text{HgCl}_2, \text{NaCl}) 0.85 \text{ Cal}$. E. C. Linebarger reported a salt $\text{NaCl} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$, but this has not been confirmed; he said the salt decomposes when treated with ethyl acetate into sodium chloride and **sodium pentachloromercuriate**, NaHg_5Cl_5 , or $\text{NaCl} \cdot 2\text{HgCl}_2$; and he accordingly prepared sodium pentachloromercuriate by the action of ethyl acetate on sodium trichloromercuriate; sodium chloride precipitates, and on evaporation of the soln., the salt in question is obtained. He also made it by mixing soln. of the component salts in ethyl acetate. The salt is said to form long needle-like crystals soluble in acetone and in ethyl acetate; it is not stable in benzene soln.; and it is only slightly dissociated in dil. soln. of acetoacetic ester between 0° and 50° . For example, E. C. Linebarger found that soln. of 2.5 (41.8°), 17.1 (48°), and 21.1 (30°) mols of mercuric chloride per litre of acetoacetic ester dissolved respectively 1.2 (41.8°), 8.4 (48°), and 10.7 (30°) mols of sodium chloride. The b.p. of the soln. of mercuric chloride in acetoacetic ether is not changed by adding sodium chloride. The salt, however, is decomposed at higher temp., and sodium chloride is precipitated. E. C. Linebarger could find no evidence of the formation of a double salt of mercuric and sodium chloride in benzene soln.

In 1822, J. Davy⁹ found a warm soln. of 7 parts of potassium chloride in 21 parts of water dissolved 8 parts of mercuric chloride, and when cooled to 15.5° , deposited a few needle-like crystals, and at 10° , it almost completely solidified to a mass of similar crystals. W. Herz and W. Paul found a soln. with 0, 2.21, and 6.83 milligram-mols of potassium chloride in 10 c.c. of water at 25° , dissolved respectively 2.65, 3.81, and 8.36 milligram-mols of mercuric chloride. A. Benrath measured the lowering of the f.p. and the raising of the b.p. of these soln., and considered that the results showed that a complex K_4HgCl_6 is present in these soln. M. le Blanc and A. A. Noyes found evidence of the formation of complexes in the electrical conductivities of mixed soln.; and O. Schönrock obtained similar evidence in the electromagnetic rotation of the plane of polarization—he found marked deviations in the results with mixed soln. of the component salts from the mixture rule.

P. A. von Bonsdorff described three double mercuric and potassium chlorides.

Writing the mol. ratio in the order $\text{HgCl}_2 : \text{KCl} : \text{H}_2\text{O}$, P. A. von Bonsdorff's three salts were 1:2:1, 1:1:1, and 2:1:2. H. W. Foote obtained similar results as the stable phases in aq. soln. of different proportions of the two component salts at 25°; but V. Tichomirowff studied the ternary system, $\text{HgCl}_2\text{—KCl—H}_2\text{O}$, at 20°, and obtained different results from H. W. Foote, for he found the anhydrous salts 1:2:0, 1:1:0, and 2:1:0. When mercuric chloride is continuously added to a sat. soln. of potassium chloride, the solubility of the latter is reduced and potassium chloride separates from the soln. After a time, the double salt $\text{HgCl}_2 \cdot 2\text{KCl}$ commences to separate; and no change in the solubility occurs until all the solid potassium chloride has been converted into this salt. Further additions of mercuric chloride again depress the solubility until the double salt $\text{HgCl}_2 \cdot \text{KCl}$ commences to separate. The phenomenon previously described is repeated with this salt; and still again with the double salt $2\text{HgCl}_2 \cdot \text{KCl}$.

H. W. Foote gave for equilibrium in the system $\text{HgCl}_2\text{—KCl—H}_2\text{O}$, at 25°:

Per cent. KCl . . .	26.46	23.74	21.39	17.85	6.66	6.27	5.77
Residue . . .	100.00	34.61	34.80	21.89	20.54	12.09	11.87
Solid phase . . .		1:2:1		1:1:1		2:1:2	

V. Tichomirowff believed that with soln. containing from no mercuric chloride and 34.41 grms. of potassium chloride up to 19.33 grms. of mercuric chloride and 41.33 grms. of potassium chloride in 100 parts of water, the solid phase is KCl; between the latter conc. and up to 42.84 grms. of mercuric chloride and 34.12 grms. of potassium chloride, the solid phase is $\text{HgCl}_2 \cdot 2\text{KCl}$; between the latter conc. and 26.41 grms. of mercuric chloride and 7.39 grms. of potassium chloride, the solid phase is $\text{HgCl}_2 \cdot \text{KCl}$; between the latter conc. and up to 26.41 grms. of mercuric chloride and 4.84 grms. of potassium chloride, the solid phase is $2\text{HgCl}_2 \cdot \text{KCl}$; and between the latter conc. and 7.39 grms. of mercuric chloride and no potassium chloride, the solid phase is HgCl_2 . V. Tichomirowff's results are shown in Fig. 17, where the solid phases of the double salts are represented as a ratio $\text{HgCl}_2 : \text{KCl}$, without showing the water of crystallization.

FIG. 17.—Solubility Curve of Aqueous Solutions of Mercuric and Potassium Chlorides, at 20°.

The results of C. Tourneux's study of the ternary system at 34°, 56°, 80°, and 100° are illustrated in Fig. 18. At 34°, the solid phases are KCl; AB , Fig. 18; $\text{HgCl}_2 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$, BC ; $\text{HgCl}_2 \cdot \text{KCl} \cdot \frac{3}{4}\text{H}_2\text{O}$, CH ; $3\text{HgCl}_2 \cdot 2\text{KCl} \cdot \frac{5}{3}\text{H}_2\text{O}$, HI ; $2\text{HgCl}_2 \cdot \text{KCl} \cdot 2\text{H}_2\text{O}$, IJ , and HgCl_2 . At 50°, the phase $2\text{HgCl}_2 \cdot 3\text{KCl} \cdot \frac{5}{3}\text{H}_2\text{O}$ has appeared, and $2\text{HgCl}_2 \cdot \text{KCl} \cdot 2\text{H}_2\text{O}$ has disappeared. The zones of stability of the different solid phases between 34° and 100° are $ABED$, for KCl; $BCFE$, for $\text{HgCl}_2 \cdot 2\text{KCl} \cdot \text{H}_2\text{O}$; CFG , for $2\text{HgCl}_2 \cdot 3\text{KCl} \cdot \frac{5}{3}\text{H}_2\text{O}$; $CHMG$, for $\text{HgCl}_2 \cdot \text{KCl} \cdot \frac{3}{4}\text{H}_2\text{O}$; $HILM$, for $3\text{HgCl}_2 \cdot 2\text{KCl} \cdot \frac{5}{3}\text{H}_2\text{O}$; and IJK , for $2\text{HgCl}_2 \cdot \text{KCl} \cdot 2\text{H}_2\text{O}$. C. Tourneux is not certain whether or not the salt $3\text{HgCl}_2 \cdot 2\text{KCl} \cdot \frac{5}{3}\text{H}_2\text{O}$ is not a solid soln. of $(2\text{HgCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O})_4(\text{HgCl}_2 \cdot 2\text{KCl} \cdot \text{H}_2\text{O})$; $\text{HgCl}_2 \cdot \text{KCl} \cdot \frac{3}{4}\text{H}_2\text{O}$, a solid soln. of $(2\text{HgCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O})(\text{HgCl}_2 \cdot 2\text{KCl} \cdot \text{H}_2\text{O})$; and $2\text{HgCl}_2 \cdot 3\text{KCl} \cdot \frac{5}{3}\text{H}_2\text{O}$, a solid soln. of $(2\text{HgCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O})(\text{HgCl}_2 \cdot 2\text{KCl} \cdot \text{H}_2\text{O})_4$. He believed the component salts of these assumed mixed crystals are homœomorphic. In acetone soln., at 25°, H. W. Foote obtained as solid phases $\text{HgCl}_2 \cdot \text{KCl} : \text{C}_3\text{H}_5\text{O}$, and the salts 5:1:1, and 6:5:2; and in ethyl alcohol soln., the solid phase $6\text{HgCl}_2 \cdot 5\text{KCl} \cdot 2\text{C}_2\text{H}_5\text{O}$.

The crystals indicated above, obtained by J. Davy, were **monohydrated potassium tetrachloromercuriate**, $K_2HgCl_4 \cdot H_2O$, or $HgCl_2 \cdot 2KCl \cdot H_2O$. J. von

FIG. 18.—Solubility Curves of Aqueous Solutions of Mercuric and Potassium Chlorides between 34° and 100°.

Cals.; $(Hg, Cl_2, 2HCl, Aq.) = 61.78$ Cals.; $(HgCl_2, 2KCl, H_2O) = 6.13$ Cals.; M. Berthelot gave $(HgCl_2, 2KCl, H_2O) = 5.40$ Cals.; $HgCl_2 \cdot 2KCl = 3.80$ Cals.; and for the heat of soln. of $HgCl_2 \cdot 2KCl$, -15 Cals., and for $HgCl_2 \cdot 2KCl, H_2O$, -16.6 Cals. J. Thomsen gives for the heat of soln. of $K_2HgCl_4 \cdot H_2O$ in $600H_2O$, -16.39 Cals.; and R. Varet, for the heat of formation in aq. soln., $(HgCl_2, 2KCl)$, 0.80 Cal.

E. C. Linebarger claimed to have made the anhydrous **potassium trichloromercuriate**, $KHgCl_3$, or $HgCl_2 \cdot KCl$, by adding gradually to a sat. soln. of mercuric chloride in acetoacetic ester an equi-molar proportion of potassium chloride. H. W. Foote made **monohydrated potassium trichloromercuriate**, $KHgCl_3 \cdot H_2O$, by shaking a soln. of the component salts; P. A. von Bonsdorff made it by digesting at 30° , a soln. of potassium chloride, sat. in the cold, with an excess of mercuric chloride. The evaporation of the clear filtrate first gives a crop of crystals of $2HgCl_2 \cdot KCl \cdot 2H_2O$, followed by a crop of crystals of $HgCl_2 \cdot KCl \cdot H_2O$. P. F. G. Boullay made the same salt by neutralizing with potassium hydroxide a soln. of mercuric chloride in hydrochloric acid. C. Tourneux obtained this salt, but he suggested that it is a solid soln. of the $2:1:2$, and the $1:2:1$ salts. The crystals are acicular, and appear in the form of four-sided prisms, which H. W. Foote recrystallized from water unchanged. P. A. von Bonsdorff said that the crystals are easily soluble in water, and sparingly soluble in alcohol. M. Berthelot gives the heat of formation $(HgCl_2, KCl)$, 2.4 Cals.; $(HgCl_2, KCl, H_2O)$, 4.2 Cals.; and for the heat of soln. of the former, -9.5 Cals., and of the latter, -11.3 Cals.

P. A. von Bonsdorff made needle-like crystals of **dihydrated potassium pentachlorodimercuriate**, $2HgCl_2 \cdot KCl \cdot 2H_2O$, or $KHg_2Cl_5 \cdot 2H_2O$, by shaking a soln. of potassium chloride, sat. at 50° to 60° , with powdered mercuric chloride, and then cooling the soln. C. F. Rammelsberg evaporated a mixed soln. of two mols of

Liebig prepared it by precipitation with alcohol from a mixed aq. soln. of potassium chloride and an excess of mercuric chloride. P. A. von Bonsdorff evaporated a soln. of eq. quantities of the two salts; and C. F. Rammelsberg a soln. of one mol of mercuric chloride with four mols of potassium chloride. According to H. W. Foote, the salt when recrystallized from water gives the $1:1:1$ salt; C. F. Rammelsberg, E. H. Kraus, and J. Graulich say that the crystals belong to the rhombic system and have axial ratios $a:b:c = 0.7074:1:0.7655$. C. Tourneux gave 3.58 for the sp. gr. at $15^\circ/15^\circ$, 0.279 for the sp. vol., and 122 for the mol. vol. J. Thomsen said that the heat of soln. of a mol of mercuric chloride in a soln. of two mols of potassium chloride is -1.38

potassium chloride with one mol of mercuric chloride. H. W. Foote made this salt by shaking the component salts with water at 25°. P. F. G. Boullay made it by neutralizing with potassium hydroxide, a sat. soln. of mercuric chloride in boiling hydrochloric acid. C. Tourneux could not make the monohydrate $2\text{HgCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$. According to H. W. Foote, the salt gives mercuric chloride when recrystallized from water. The rhombic crystals when heated in open vessels lose their contained mercuric chloride; they are very soluble in warm water, and sparingly soluble in alcohol. C. Tourneux gave 4.11 for the sp. gr. at 15°/15°, 0.243 for the sp. vol., and 159 for the mol. vol. M. Berthelot gave the heats of formation of some imaginary salts 3:4:0, 3:4:3, and 1:4:0.

R. Godefroy prepared the double salts of mercuric and rubidium chlorides with $\text{HgCl}_2 \cdot \text{RbCl} \cdot \text{H}_2\text{O}$ in the ratio 1:2:0, 1:2:2, and 1:1:0, but H. W. Foote and L. H. Levy were unable to obtain any of these, for they found that at 25°, the solid phases in aq. soln. are the 5:1:0, 4:3:1, 1:1:1, 2:3:2, and the 1:2:1 salts, although H. W. Foote and L. H. Levy's salt 1:2:1 lies between R. Godefroy's 1:2:0 and 1:2:2. According to H. W. Foote and L. H. Levy, the percentage solubilities of rubidium and mercuric chlorides are respectively 48.57 and 6.90 at 25°; and the ranges of stabilities of the solid phases for different percentage compositions of the soln. are:

RbCl . . .	47.65	35.16	30.27	29.20	23.81	10.87	10.06	5.10	2.98	1.10
HgCl_2 . .	10.35	19.58	20.17	20.55	18.71	10.42	9.86	8.33	7.71	7.21
Solid phases .	1:2:1		2:3:2		1:1:1		4:3:1		5:1:0	

H. W. Foote and L. H. Levy's curve, shown in Fig. 19, indicates the range of stability for **rubidium henadecachloropentamercuriate**, $5\text{HgCl}_2 \cdot \text{RbCl}$, or

FIG. 19.—Compositions of Aqueous Solutions of Cesium or Rubidium and Mercuric Chlorides in Equilibrium with the Solid Phases (25°).

$\text{RbHg}_5\text{Cl}_{11}$; when this salt is recrystallized from water, it gives crystals of mercuric chloride. R. Godefroy claimed to have prepared silky needle-like crystals of **rubidium pentachlorodimercuriate**, $2\text{HgCl}_2 \cdot \text{RbCl}$, or RbHg_2Cl_5 , by evaporating a soln. with equal parts by weight of the component salts, but H. W. Foote and L. H. Levy did not find this salt amongst the solid phases in equilibrium with aq. soln at 25°; rather did they obtain silky crystals of **monohydrated rubidium henadecachlorotetramercuriate**, $4\text{HgCl}_2 \cdot 3\text{RbCl} \cdot \text{H}_2\text{O}$, or $\text{Rb}_3\text{Hg}_4\text{Cl}_{11} \cdot \text{H}_2\text{O}$, from soln. with the composition indicated in the above table. C. Tourneux also made this salt. It gives the 5:1 salt when recrystallized from water. R. Godefroy made **rubidium trichloromercuriate**, $\text{HgCl}_2 \cdot \text{RbCl}$, or RbHgCl_3 , by heating $\text{RbCl} \cdot 2\text{HgCl}_2$ to 150° when mercuric chloride is volatilized and RbHgCl_3 remains. H. W. Foote and L. H. Levy made the monohydrated salt from soln. with the composition indicated in the preceding table. C. Tourneux also made this salt. When recrystallized from water, this salt furnishes the 4:3:1 salt. The same investigators obtained **dihydrated rubidium heptachloro-dimercuriate**, $2\text{HgCl}_2 \cdot 3\text{RbCl} \cdot 2\text{H}_2\text{O}$, or $\text{Rb}_3\text{Hg}_2\text{Cl}_7$, from soln. with the composition indicated in the preceding table; and it yields the 4:3:1 salt when recrystallized from water. R. Godefroy reported that needle-like crystals of **tetrahydrated rubidium tetrachloromercuriate**, $\text{HgCl}_2 \cdot 2\text{RbCl}$, or

Rb_2HgCl_4 , separated by evaporating the hydrochloric acid soln. of the constituents, and he also reported colourless prisms of the dihydrated salt to be formed by the evaporation of an aq. soln. of the anhydrous salt; but H. W. Foote and L. H. Levy could get only the monohydrated salt from soln. whose composition is indicated in the preceding table. When recrystallized from water it gives the 4 : 3 : 1 salt.

R. Godeffroy reported the double salt $\text{HgCl}_2 \cdot 2\text{CsCl}$ in 1875; and H. L. Wells prepared five double salts of mercuric and caesium chlorides with $\text{HgCl}_2 : \text{CsCl}$, all of which—5 : 1, 2 : 1, 1 : 1, 1 : 2, and 1 : 3—were anhydrous in aq. soln. at 25° . It might have been expected that caesium, the extreme member of the potassium groups, and the most electropositive of the metals, would form a more complete series of double salts than the other alkali metals, and this the more because the caesium double salts are usually less soluble than the corresponding salts of the other alkali metals. It will also be observed that the variety of the caesium double salts is greater with mercury than with cadmium, since mercury gives six types of halide double salts, while cadmium gives but three. Zinc also gives but two and magnesium one. Hence, the variety of double salts with these bivalent elements increases with the at. wt. of the element. Representing the ratios $\text{HgCl}_2 : \text{MCl} : \text{H}_2\text{O}$ in the double salts of mercuric and the alkali chlorides, the following scheme indicates those salts whose existence as chemical individuals is fairly well established :

NaCl	NH_4Cl	KCl	RbCl	CsCl
..	5 : 1 : 0	5 : 1 : 0
..	9 : 2 : 0
..	..	2 : 1 : 1	..	2 : 1 : 0
..	3 : 2 : 1
..	4 : 3 : 1	..
1 : 1 : 1	1 : 1 : 1	1 : 1 : 1	1 : 1 : 1	1 : 1 : 0
..	1 : 3 : 2	..
..	1 : 2 : 1	1 : 2 : 1	1 : 2 : 1	1 : 2 : 0
..	1 : 3 : 0

C. Tourneux added that the double salts are all homœomorphic, and show marked chemical analogies. The dehydration curves show analogies with those of the zeolites, and suggest that the water content of the crystals depends on the vap. press. of the surrounding atm.

H. W. Foote applied the phase rule solubility method to aq. soln. of caesium and mercuric chlorides, and the solid phases were found to be the same as those described by H. L. Wells. According to H. W. Foote, the percentage solubilities of caesium and mercuric chlorides are 65.61 and 6.90, respectively, at 25° ; and the ranges of stability of the solid phases for soln. of different percentage composition are :

CsCl	.	62.36	52.35	49.30	45.95	38.63	1.53	0.49	0.40	0.41	0.25
HgCl_2	.	0.32	1.23	1.49	1.69	1.32	0.42	2.91	3.78	4.68	5.65
Solid phases	.	1 : 3		1 : 2		1 : 1		2 : 1		5 : 1	

A portion of the curve for the ranges of stability is shown in Fig. 18. The experimental results with mixtures of caesium and mercuric chlorides are illustrated by the graph, Fig. 20. The vertical lines—soln. variable, residue constant—correspond with the five double salts $\text{CsCl} : \text{HgCl}_2$ as 3 : 1, 2 : 1, 1 : 1, 1 : 2, 1 : 5, which are therefore stable in aq. soln. at 25° . The horizontal lines—soln. constant, residue variable—indicate mixtures of salts represented by the adjacent vertical lines. There was an irregularity observed in the numbers relating to the 1 : 1 salt, $\text{CsCl} \cdot \text{HgCl}_2$ or CsHgCl_3 , for the experiments showed at first a slight decrease and then a slight increase in the proportion of mercuric chloride along the CsHgCl_3 line. This corresponding with a change in the nature of the double salt in spite of a change in composition. This change is presumably connected with the known dimorphism—cubic and rhombic—of this salt; there is only one definite transition temp. at which both forms are stable, and it might therefore be expected that one form alone would

appear at the arbitrary temp. 25° . However, the conditions are not the same in different experiments: When the caesium salt largely predominates, the cubic form is stable; if otherwise, the rhombic form is stable. According to the phase rule, when the double salt is present there are four phases in the system—two solids, soln., vapour—and three components. The system is therefore univariant. If the temp. be variable, the conc. of the soln. will remain constant, and if one phase disappears, the soln. becomes bi-variant, when both temp. and conc. may be varied.

H. L. Wells made **caesium henadecachloropentamercuriate**, $5\text{HgCl}_2 \cdot \text{CsCl}$, or $\text{CsHg}_5\text{Cl}_{11}$, by cooling a boiling aq. soln. of a mol of caesium chloride with six mols of mercuric chloride. D. Strömholm prepared it by the action of a soln. of mercuric and caesium chlorides in ethylsulphine chloride, $(\text{C}_2\text{H}_5)_3\text{SCl}$. According to S. L. Penfield, the prismatic crystals are monoclinic with the axial ratios $a:b:c=0.7233:1.04675$, and $\beta=85^{\circ} 51' 40''$. According to H. W. Foote and L. H. Levy, when recrystallized from water it furnishes the 2:1 salt. H. L. Wells also made **caesium pentachlorodimercuriate**, $2\text{HgCl}_2 \cdot \text{CsCl}$, or CsHg_2Cl_5 , by cooling a soln. of 24 grms. of CsHgCl_2 and 16 grms. of mercuric chloride in hot water. According to H. W. Foote and L. H. Levy, when recrystallized from water it furnishes the 1:1 salt. According to S. L. Penfield, the monoclinic prismatic crystals have the axial ratios $a:b:c=1.6099:1.13289$, and $\beta=101^{\circ} 6'$. As indicated above, **caesium trichloromercuriate** is dimorphous. Cubic crystals of the salt are formed by cooling mixed soln. with a large excess of caesium chloride or by crystallizing the salt from a soln. of alcohol (1:3). It is almost insoluble in absolute alcohol. The rhombic crystals are deposited when the caesium chloride is not in excess, and by one or more crystallizations from water of any of the double caesium chlorides. According to S. L. Penfield, the axial ratios are $a:b:c=0.5774:1.04088$; and the refractive index $\mu=1.779$ for the lithium ray, and 1.792 for the sodium ray. The salt can be recrystallized from water unchanged, and at 17° , the aq. soln. contains 1.406 per cent. of this salt. R. Godeffroy made **caesium tetrachloromercuriate**, $\text{HgCl}_2 \cdot 2\text{CsCl}$, or Cs_2HgCl_4 , by mixing soln. of the constituents in hydrochloric acid, and H. L. Wells by crystallization from a hot soln. of mercuric chloride in a nearly sat. soln. of caesium chloride. The crystal constants have not been measured. The salt is very soluble in water. When recrystallized from water, crystals of the 1:1 salt are formed. H. L. Wells also made pyramidal prismatic crystals of **caesium pentachloromercuriate**, $\text{HgCl}_2 \cdot 3\text{CsCl}$, or Cs_3HgCl_5 , by dissolving a comparatively small quantity of mercuric chloride in a rather less quantity of a nearly sat. soln. of caesium chloride than is required for the preceding salt. H. W. Foote's work on the mutual solubility of mercuric and caesium chlorides shows the conditions of stability. S. L. Penfield found the crystals belong to the rhombic system and have the axial ratios $a:b:c=0.7976:1.06605$. When crystallized from water it gives the 1:1 salt.

P. A. von Bonsdorff¹⁰ reported the formation of a double salt, **cupric tetrachloromercuriate**, $\text{HgCl}_2 \cdot \text{CuCl}_2$, by mixing aq. soln. of the component salts, and T. Harth also claimed to have made it in greenish-blue needle-like crystals by evaporating a soln. sat. with both components. The crystals are easily soluble in water, they are probably mixed crystals because, in spite of R. Varet's values for the heats of formation in soln.— $(\text{CuCl}_2, \text{HgCl}_2)$, 1.2 Cals. at 18° , and $(\text{CuCl}_2, 2\text{HgCl}_2)$, 1.36 Cals. at 17° —F. A. H. Schreinemakers and J. C. Thonus could find no evidence of the

FIG. 20.—Solid Phases with Solutions of Mercuric and Cæsium Chlorides.

formation of a double salt in aq. soln. at 35° when examined by the solubility method. The isothermal line *ac* in Fig. 21 represents soln. sat. with $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$;

FIG. 21.—Solubility curves in the Ternary System, CuCl_2 — HgCl_2 — H_2O at 35°.

and *bc*, soln. sat. with HgCl_2 . The point of intersection *c* represents soln. sat. with both these salts. The solubility of mercuric chloride, *bc*, Fig. 21, is greatly increased by the addition of cupric chloride rising from 8.5 per cent. in water alone to 52.8 per cent. when 18.06 per cent. of cupric chloride is present. P. A. von Bonsdorff also claimed to have made rhombic crystals of the ternary salt, $3\text{HgCl}_2 \cdot \text{CuCl}_2 \cdot 6\text{KCl} \cdot 2\text{H}_2\text{O}$, by crystallization from mixed soln. of $\text{HgCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$ and $\text{CuCl}_2 \cdot \text{KCl} \cdot \text{H}_2\text{O}$. A. Mailhe also reported two *cupric mercuric oxychlorides*, $3\text{CuO} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$ and $7\text{CuO} \cdot \text{CuCl}_2 \cdot \text{HgCl}_2 \cdot 2\text{H}_2\text{O}$, which are probably mixtures.

The chloromercuriates of the alkaline earths have not been so closely investigated as those of the alkali metals. W. Herz and W. Paul have studied the solubilities of mercuric chloride in soln. of the chlorides of the alkaline earths; T. W. Richards and E. H. Archibald found that when calomel is shaken with soln. of barium or calcium chloride, the dissolved mercury exists wholly in the mercuric state. As the conc. of the calcium or barium chloride is increased, the quantity of mercuric chloride in soln. increases as a simple function of the square of the conc. of the chlorine ions. The results are explained by assuming that a highly ionized complex CaHgCl_4 or BaHgCl_4 is produced. P. A. von Bonsdorff reported octahedral crystals of **octohydrated calcium dodecachloropentamercuriate**, $\text{CaCl}_2 \cdot 5\text{HgCl}_2 \cdot 8\text{H}_2\text{O}$, or $\text{CaHg}_5\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$, to be formed by the slow evaporation of a soln. of calcium chloride not completely sat. with mercuric chloride. D. Strömholm also made analogous crystals by a similar process which his analyses represented as $\text{CaCl}_2 \cdot 6\text{HgCl}_2 \cdot 6\text{H}_2\text{O}$. P. A. von Bonsdorff made rhombic plates of **hexahydrated calcium hexachloromercuriate**, $\text{CaCl}_2 \cdot 2\text{HgCl}_2 \cdot 6\text{H}_2\text{O}$, by crystallization from a soln. of calcium chloride sat. with mercuric chloride. R. Varet gave the heat of formation in soln. at 17° as 0.98 Cal. P. A. von Bonsdorff prepared needle-like crystals of what he regarded as **strontium hexachlorodimercuriate**, $\text{SrCl}_2 \cdot 2\text{HgCl}_2 \cdot 2\text{H}_2\text{O}$, by the evaporation of sat. soln. of the component salts. J. N. Swan believed that P. A. von Bonsdorff's salt just described is really $\text{SrCl}_2 \cdot 3\text{HgCl}_2 \cdot 5$ (or 6) H_2O . R. Varet computed the heat of formation in soln. at 17° to be 0.98 Cal. T. Harth's salts with the ratio $\text{HgCl}_2 : \text{SrCl}_2$ as 8 : 1, 8 : 5, 3 : 2, and 4 : 3 are probably mixtures.

J. Davy, in 1822, prepared crystals of what has been regarded as a double salt of barium and mercuric chlorides by dissolving 20 parts of mercuric chloride in a hot soln. of 8.7 parts of dihydrated barium chloride in 20 parts of water. P. A. von Bonsdorff obtained oblique rhombic prisms in a somewhat similar way, and his analyses correspond with $\text{BaCl}_2 \cdot 2\text{HgCl}_2 \cdot 2\text{H}_2\text{O}$, but J. N. Swan believed these crystals have rather the composition $\text{BaCl}_2 \cdot 3\text{HgCl}_2 \cdot 8\text{H}_2\text{O}$. H. W. Foote and H. S. Bristol, however, by an application of the solubility method, said that in aq. soln., at 25°, there is evidence of the formation of **hexahydrated barium octochlorotrimercuriate**, $\text{BaCl}_2 \cdot 3\text{HgCl}_2 \cdot 6\text{H}_2\text{O}$, or $\text{BaHg}_3\text{Cl}_8 \cdot 6\text{H}_2\text{O}$, but not of P. A. von Bonsdorff's salt. This also agrees with F. A. H. Schreinemakers' observations. R. Varet has calculated the heat of formation of some possible barium chloromercuriates. C. Sandonnini observed no double compounds of strontium or barium chloride on the f.p. curves.

P. A. von Bonsdorff obtained rhombic crystals of **beryllium chloromercuriate** by the evaporation of an aq. soln. of the component salts, but he gave no analyses. A. Atterberg likewise obtained tabular hygroscopic crystals by evaporating a soln.

of equi-equivalents of the two chlorides in an excess of hydrochloric acid, but J. C. G. de Marignac claims that no double salt is formed since he obtained crystals of mercuric chloride alone. J. Davy obtained a crop of needle like crystals by dissolving mercuric chloride in a warm soln. of magnesium chloride of sp. gr. 1.58; J. N. Swan found the crystals have the composition $\text{MgCl}_2 \cdot 3\text{HgCl}_2 \cdot 6\text{H}_2\text{O}$; and P. A. von Bonsdorff likewise obtained crystals of **magnesium octochlorotrimercuriate**, $\text{MgCl}_2 \cdot 3\text{HgCl}_2 \cdot 5(\text{or } 6)\text{H}_2\text{O}$, by evaporating a soln. of magnesium chloride sat. with mercuric chloride, and from the mother liquid he obtained rhombic prisms of **magnesium tetrachloromercuriate**, $\text{MgCl}_2 \cdot \text{HgCl}_2 \cdot 6\text{H}_2\text{O}$. W. Herz and W. Paul have studied the solubility of mercuric chloride in soln. of magnesium chloride. F. Calzolari and U. Tagliavini obtained crystals of a complex of $\text{MgCl}_2 \cdot 2\text{HgCl}_2 \cdot 10\text{H}_2\text{O}$ with hexamethylenetetramine. R. Varet has computed the heats of formation of some possible double salts of magnesium and mercuric chlorides. According to P. A. von Bonsdorff, a soln. of mercuric chloride in an aq. soln. of zinc chloride on evaporation first deposits crystals of mercuric chloride, then deliquescent needles and plates of **zinc chloromercuriate** slowly separate out. C. Sandonnini found molten zinc and mercuric chlorides are incompletely miscible; two layers are formed each containing traces of the other constituent. K. Drucker measured the conductivity, distribution numbers, and the depression of the f.p. of aq. soln. of zinc and mercuric chlorides, and concluded that soln. with over 0.05 mol of these salts per litre contain a mixed complex which in the non-ionized condition contains four chlorine atoms, and is, in consequence, probably ZnHgCl_4 , a compound which T. Harth claims to have prepared, but he gives no analyses. R. Varet has calculated the heats of formation of some possible zinc chloromercuriates; for $(\text{ZnCl}_2, \text{HgCl}_2)$ in aq. soln. at 17° , he gives 1.14 Cals. G. André has reported two **zinc amino-chloromercuriates**, namely, $2\text{ZnCl}_2 \cdot \text{HgCl}_2 \cdot 6\text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, and $4\text{ZnCl}_2 \cdot \text{HgCl}_2 \cdot 10\text{NH}_3 \cdot 3\text{H}_2\text{O}$. A. Mailhe has reported the oxychloride $\text{CdO} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$; and R. Varet has calculated the heats of formation of some possible *cadmium chloromercuriates*.

§ 16. Ammoniobasic and Aquo-ammonio-basic Salts of Mercuric Chloride

In the thirteenth century, Raymond Lully¹ obtained a *fusible white precipitate—perfectum precipitatum*—by treating mercuric nitrate with sal ammoniac and salt of tartar; this precipitate was later confused with calomel prepared by the wet process, and also with an infusible white precipitate obtained by N. Lemery by the action of ammonia on a soln. of mercuric chloride. Although J. Kunckel called both precipitated calomel and the fusible white precipitate *lac mercurii*, he said they are very different in *examine chymico*; and F. Wöhler and R. J. Kane (1837) made clear the difference between all three preparations.

A great many different opinions have been promulgated as to the constitution or composition of infusible white precipitate, and in accord therewith it has been called by many different names. C. F. Rammelsberg and L. Pesci regarded it as a compound of ammonium chloride, NH_4Cl , with mercuriammonium chloride, $\text{NH}_2\text{Hg}_2\text{Cl}$, which was formed. H. Gaudechon² tried to show that it is a complex analogous with

The general opinion now is that this compound is mercuric chloroamide, $\text{Hg}(\text{NH}_2)\text{Cl}$, or amido-mercuric chloride, $\text{NH}_2\text{Hg}\cdot\text{Cl}$; and is formed by the aminolysis of

mercuric diammino-chloride, $\text{HgCl}_2 \cdot 2\text{NH}_3$, by a process analogous to the hydrolysis of salts. The aminolytic decomposition is symbolized: $\text{HgCl}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{NH}_4\text{Cl} + \text{NH}_2\text{HgCl}$, and this emphasizes how the aminolysis is reversed by the accumulation of ammonium chloride in the system. While many amido-compounds are hydrolytically decomposed in the presence of water—*e.g.* potassamide—and can be formed from liquid ammonia or in the presence of solvents other than water, the compounds formed by the action of ammonia on mercuric salts can usually exist in the presence of water without appreciable hydrolysis.

In 1792, A. F. de Fourcroy described the preparation of mercuric chloroamide by the action of ammonia on mercuric chloride, and stated this substance is decomposed by heat into nitrogen, ammonia, and mercurous chloride. A similar method was used by H. Hennell and R. Brandes in 1825, and by R. J. Kane in 1836. An aq. soln. of mercuric chloride is treated with a slight excess of ammonia. The precipitate is washed with a small quantity of cold water, pressed between paper, and dried at a gentle heat. If the precipitate be washed with too much water, particularly with hot water, it acquires a yellow colour, owing to the formation of the chloride of the so-called Millon's base: HO.Hg.NH.HgCl ; the hydrolytic reaction is represented: $2\text{NH}_2\text{HgCl} + \text{H}_2\text{O} = \text{NH}_4\text{Cl} + \text{HO.Hg.NH.HgCl}$. H. Hennell said that if 272 parts of mercuric chloride be precipitated by aq. ammonia containing 34 parts of ammonia, the filtrate is a soln. of neutral ammonium chloride; and G. Krug, that if the precipitation be made in the cold, and the precipitate rapidly separated from the mother liquid, a fairly pure product is obtained. R. J. Kane found that 270.8 parts of mercuric chloride furnish 252.2 parts and P. Geiseler 254.6 parts of infusible white precipitate. C. Tanret says that a white precipitate of this salt is formed when a 1 : 1000 soln. of mercuric chloride stands in air containing ammonia. H. Saha and K. N. Choudhuri dissolved freshly precipitated mercuric chloroamide in aqua ammonia, and evaporated the soln. over sulphuric acid in vacuo. The aggregates of small prismatic crystals were then washed with a little water, dried first in a desiccator, and finally at 100° .

Many other modifications of R. J. Kane's process have been described by G. André, E. Balestra, J. Sen, D. Strömholm, E. C. Franklin, etc. N. A. E. Millon, for example, dropped the mercuric chloride soln. into an excess of ammonia and, according to G. André, if N. A. E. Millon's procedure be followed with cold soln. of 33.875 grms. of mercuric chloride, and 4.25 grms. of ammonia per litre, and the precipitate be rapidly washed with cold water, a purer product is obtained than if R. J. Kane's process be used; he added that if an appreciable amount of hydrolysis has taken place, the precipitate, dried at 110° , will evolve water if heated to a higher temp.

E. C. Franklin obtained mercuric chloroamide by treating mercuric chloride with an excess of liquid ammonia, pouring off the excess of ammonia, and then washing the residue. There is a reaction: $\text{HgCl}_2 + 2\text{NH}_3 \rightleftharpoons \text{Hg}(\text{NH}_2)\text{Cl} + \text{NH}_4\text{Cl}$. In the liquid ammonia, the presence of a small quantity of ammonium chloride hinders the formation of the mercuric chloroamide, but in aq. soln., a large excess of ammonium chloride is needed to hinder its formation. D. Strömholm prepared mercuric chloroamide by agitating a mixture of mercuric diammino-chloride with aq. ammonia for five days until the conc. of the ammonium chloride remained constant. A. Duflos likewise obtained infusible white precipitate by adding ammonium carbonate to a soln. of mercuric chloride; *au contraire*, added G. S. Johnson, ammonium carbonate is far more potent than ammonium chloride in preventing the precipitation, for, even after complete precipitation, the addition of an excess of ammonium carbonate causes the precipitate to dissolve; he said that even the little carbon dioxide absorbed when it has stood in a loosely stoppered bottle, makes it unfit for the preparation of infusible white precipitate. D. J. Carnegie and F. Burt prepared it by treating a soln. of mercuric chloride with ammonium oxalate and sodium or ammonium phosphate. F. L. Winckler converted mercuric oxychloride into the chloroamide by agitating it with conc. aqua ammonia; and R. Varet

similarly converted mercuric chlorocyanide; E. C. Franklin agitated for some days the soln. of mercuric chloride in liquid ammonia with sodium amide, and the resulting product was washed to remove the sodium chloride and the excess of mercuric ammino-chloride. C. Barfoed found that the black product obtained by the action of ammonia on mercurous chloride when exposed to air in thin layers gradually loses mercury and becomes white or almost white mercuric chloroamide; and H. Saha and K. N. Choudhuri showed that the last-named salt can be dissolved from the black product by digesting it with conc. aqua ammonia.

As A. F. de Fourcroy³ stated, mercuric chloroamide is a white powder which at first has an earthy taste and which afterwards appears to have the so-called metallic taste. H. Saha and K. N. Choudhuri obtained this salt in aggregates of small prismatic crystals. H. Gaudechon says the heat of formation of the reaction is: $\text{NHg}_2\text{Cl} + \text{NH}_4\text{Cl} = 2\text{Hg}(\text{NH}_2)\text{Cl} + 6.8 \text{ Cals.}$ P. C. Ray and N. R. Dhar measured the electrical conductivity of aq. soln., and from the results inferred that the salt is decomposed into simpler parts, namely, NHg_2Cl and NH_4Cl . R. J. Kane showed that while mercuric chloroamide does not dissolve in water, it is slowly decomposed into a yellow product by cold water, and very quickly by boiling water; he found 502.8 parts of the white precipitate yield 450.3 parts of the yellow powder when treated with boiling water, and the water has taken up 51.5 parts of ammonium chloride. G. André has studied the progressive action of water on mercuric chloroamide, and has shown that the precipitate is gradually hydrolyzed, and D. Strömholm and H. Gaudechon have shown that with water there is a reversible reaction involving the formation of the chloride of Millon's base: $2\text{Hg}(\text{NH}_2)\text{Cl} + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4\text{Cl} + \text{HO.Hg.NH.Hg.Cl}$, followed by the hydrolysis of the chloride of Millon's base: $\text{HO.Hg.NH.Hg.Cl} + \text{H}_2\text{O} \rightleftharpoons 2\text{HgO} + \text{NH}_4\text{Cl}$. The hydrolysis progresses more quickly if the water be hot, and in boiling water the reaction $2\text{Hg}(\text{NH}_2)\text{Cl} + \text{H}_2\text{O} = \text{NH}_4\text{Cl} + \text{HO.Hg.NH.Hg.Cl}$ is virtually completed in a few minutes.

When mercuric chloroamide is heated, very gently to about 340° , E. Mitscherlich found that some ammonia is first evolved without a trace of nitrogen, then follows the sublimation of mercuric chloride, and a red substance, $\text{NHg}_2\text{Cl.HgCl}_2$, remains. Consequently, the reaction is symbolized: $3\text{Hg}(\text{NH}_2)\text{Cl} = 2\text{NH}_3 + \text{HgCl}_2 + \text{NHg}_2\text{Cl}$, when heated below redness. R. J. Kane found mercuric chloroamide to be resolved without fusion into about 93 per cent. of mercurous chloride, and a mixture of one volume of nitrogen and two volumes of ammonia. This result has been confirmed by J. Sen, who found that two-thirds of the contained nitrogen is converted into ammonia, and one-third into nitrogen:

There are secondary reactions, for the mercurous chloride is usually blackened by the ammonia and some ammonium chloride is formed: $2\text{NH}_3 + 2\text{HgCl} = \text{NH}_4\text{Cl} + \text{Hg} + \text{NH}_2\text{HgCl}$.

According to H. Saha and K. N. Choudhuri, cold aq. *hydrofluoric acid* gives a mixture of ammonium fluoride and a fluorochloride, HgFCl . V. Schwarzenbach found that when mercuric chloroamide is exposed to the action of gaseous *chlorine* or chlorine water, all the contained nitrogen is evolved as a gas, and the mercury forms mercuric chloride; if the powder be projected into a globe filled with chlorine gas, it becomes hot and either explodes or produces a green flame—presumably owing to the formation of some nitrogen chloride. According to C. Ullgren, dry *hydrogen chloride* at 100° transformed the salt into a mixture of ammonium and mercuric chlorides—no water or mercuric oxide is formed— $\text{Hg}(\text{NH}_2)\text{Cl} + 2\text{HCl} = \text{HgCl}_2 + \text{NH}_4\text{Cl}$. A. F. de Fourcroy found it to be soluble in *hydrochloric acid*, forming a soln. of mercuric and ammonium chlorides, as was further established by H. Saha and K. N. Choudhuri. C. F. Rammelsberg found that a boiling conc.

soln. of *alkali chloride* separates ammonia from this compound, and mercuric chloride passes into soln., and G. André separated the nitrogen quantitatively as ammonia by this reaction. According to R. H. Brett, it is soluble in a hot soln. of *ammonium chloride*, and E. C. Franklin found that it is in equilibrium with a 0.49N-soln. of ammonium chloride: $\text{HgCl}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{Hg}(\text{NH}_2)\text{Cl} + \text{NH}_4\text{Cl}$; and for the reversible reaction, $2\text{Hg}(\text{NH}_2)\text{Cl} + \text{H}_2\text{O} \rightleftharpoons \text{HO} \cdot \text{Hg} \cdot \text{NH} \cdot \text{Hg} \cdot \text{Cl} + \text{NH}_4\text{Cl}$, the conc. of the ammonium chloride is less. R. J. Kane found mercuric chloroamide to be decomposed when boiled with *cupric chloride*; a precipitate of the so-called Brunswick green, $\text{CuCl}_2 \cdot 3\text{CuO}$, and a soln. of alembroth salt is formed. V. Schwarzenbach found that *bromine* acts like chlorine without forming nitrogen bromide; according to H. Edhem-Bey, a dil. alcoholic soln. of bromine acts vigorously on mercuric chloroamide, forming carbon tetrachloride, and a double salt, $\text{NH}_4\text{Cl} \cdot \text{HgBr}_2$. Cold *hydrobromic acid*, said H. Saha and K. N. Choudhuri, gives a mixture of mercuric and ammonium bromides. According to K. A. Hofmann and E. C. Marburg, with a soln. of *ammonium bromide* ammonia is evolved. F. A. Flückiger noted that *hypobromous acid* or the alkali hypobromites decompose mercuric chloroamide in the presence of water, but less violently than iodine. H. Saha and K. N. Choudhuri say cold *hydriodic acid* gives a mixture of mercuric and ammonium iodides. According to V. Schwarzenbach, a mixture of finely divided mercuric chloroamide and an ethyl alcohol soln. of *iodine* first forms mercuric iodide, and then explodes with great violence; but dry iodine does not explode when rubbed up with mercuric chloroamide, or when the mixture is subjected to percussion, but F. A. Flückiger did obtain a detonation from a mixture of three parts of mercuric chloroamide and four parts of iodine which had been vigorously triturated and allowed to stand some time—iodine and nitrogen were developed. If two parts of iodine, in soln. in carbon disulphide, chloroform, glycerol, amyl or propyl alcohol in place of ethyl alcohol, be mixed with five of mercuric chloroamide, V. Schwarzenbach obtained no explosion in 24 hrs., but with six of iodine he did get an explosion owing to the formation of some nitrogen iodide. A mixture of water, iodine, and mercuric chloroamide decrepitated; F. A. Flückiger represented the reaction: $9\text{Hg}(\text{NH}_2)\text{Cl} + 6\text{I}_2 = 3\text{HgCl}_2 + 6\text{HgI}_2 + 3\text{NH}_4\text{Cl} + 2\text{NH}_3 + 2\text{N}_2$, and he adds that some nitrogen iodide, NH_2I , is formed as an intermediate product; according to C. Rice, the formation of explosive nitrogen iodide is prevented if some phenol be present, and iodoform, CHI_3 , is then formed. R. J. Kane said that with an aq. soln. of *potassium iodide*, ammonia and mercuric iodide are formed. According to E. Rupp and F. Lehmann, the reaction is: $\text{Hg}(\text{NH}_2)\text{Cl} + 2\text{KI} + \text{H}_2\text{O} = \text{HgI}_2 + \text{KCl} + \text{NH}_3 + \text{KOH}$.

According to V. Schwarzenbach, if mercuric chloroamide be heated to 150° with one-eighth of its weight of sulphur, the mixture becomes brown and a purple-red vapour of nitrogen sulphide, N_4S_4 , is evolved; with equal weights of the two, the mixture becomes yellow at 150° , and a purple-red vapour of E. Soubeiran's *chloride de soufre ammoniacal*, $\text{SCl}_2 \cdot 2\text{NH}_3$, is formed. R. J. Kane found that when mercuric chloroamide is heated with an aq. soln. of *barium sulphide*, ammonia and mercuric sulphide are formed. A. F. de Fourcroy noted that mercuric chloroamide is soluble in *sulphuric acid*, forming mercuric chloride, and mercuric and ammonium sulphates; according to C. Kosmann, if mercuric chloroamide be boiled with water acidified with sulphuric acid, and the soln. evaporated on a water-bath, white plate-like crystals of the triple salt, $2\text{NH}_4\text{Cl} \cdot 2\text{HgSO}_4 \cdot \text{HgCl}_2$, are formed, mercuric and ammonium sulphates remain in soln. According to G. André, dil. sulphuric acid does not decompose the salt even at 225° in a sealed tube. R. J. Kane could detect no reaction between *ammonia* and mercuric chloroamide, while D. J. Carnegie and F. Burt found mercuric chloroamide to be insoluble in an excess of ammonia; but H. Saha and K. N. Choudhuri found that if freshly precipitated the chloroamide dissolves in conc. aqua ammonia, and can be recovered in a crystalline form by evaporation. A. F. de Fourcroy and C. Kosmann found the salt to be soluble in dil. *nitric acid*, forming mercuric nitrate and ammonia; and R. H. Brett, soluble in a warm aq. soln. of *ammonium nitrate*, and, according to K. A. Hofmann and

E. C. Marburg, ammonia is slowly evolved. According to K. A. Hofmann and E. C. Marburg, with a neutral soln. of *silver nitrate* it gives up only half the contained chlorine during a 30 mins.' digestion; L. Pesci says the whole of the chlorine is given up by this treatment. B. E. Howard found that *hypophosphorous acid* reduces mercuric chloroamide to the metal when the mixture is warmed on a water-bath. D. J. Carnegie and F. Burt found that the salt is soluble in a conc. soln. of *phosphoric acid*, and the soln. deposits crystals of a compound not yet identified; it is also soluble in an excess of a soln. of *diammonium hydrogen phosphate*, but not in a soln. of *disodium hydrogen phosphate*. According to C. Reichard, a soln. of *arsenious oxide* in ammonia reduces mercuric chloroamide in a short time, and the colour changes from white to grey to black owing to the separation of mercury.

H. Hennell found mercuric chloroamide to be soluble in *hydrocyanic acid*; V. Schwarzenbach found that when heated with a soln. of potassium cyanoplatinite, K_2PtCy_4 , it furnishes a soln. of *ammonium cyanoplatinite*, and the yellow chloride of Millon's base, $HO.Hg.NH.HgCl$; C. Kosmann found that when boiled with twice its weight of *potassium hydrogen oxalate*, carbon dioxide and insoluble mercuric oxalate, $Hg_2C_2O_4$, are formed: $4KHC_2O_4 + 2Hg(NH_2)Cl = 2CO_2 + 2NH_4Cl + 2K_2C_2O_4 + Hg_2C_2O_4$; and when boiled with a soln. of *potassium hydrogen tartrate*, $KH_5C_4O_6$, carbon dioxide is evolved. H. Bauer says that it dissolves without residue in acetic acid of sp. gr. 1.060; and C. Kosmann showed that when the soln. is boiled, mercury and carbon dioxide are formed, while yellow crystals are formed when the soln. is evaporated.

According to V. Schwarzenbach, *ethyl chloride* does not react with mercuric chloroamide at ordinary temp. and press.; but when heated, H. Köhler recognized ethylamine, mercuric and mercurous chlorides among the products of decomposition. *Acetyl chloride* reacts vigorously when heated therewith, forming the corresponding amide. E. Schmidt and L. Krauss obtained by the action of mercuric chloroamide on a soln. of *methyl iodide* in methyl alcohol at room temp. for a long time a double compound of tetramethylammonium and mercuric iodides: $2N(NH_3)_4I.3HgI_2$; and when heated for 2 hrs. in a sealed tube on a water-bath, a compound $N(CH_3)_4I.HgI_2$. F. L. Sonnenschein observed among the products of the action of *ethyl iodide* heated with mercuric chloroamide for many days, (i) an *aqueous solution* of mercuric and ammonium chlorides and a crystalline compound of mercuric chloride with ethylamine hydrochloride; (ii) a heavy dark brown liquid containing the excess of ethyl iodide, from which alcoholic ether extracts a double compound of mercuric iodide with ethyl-, diethyl-, triethylamine hydroiodides, and tetraethylammonium iodide; and (iii) crystals of a double compound of mercuric iodide with tetraethylammonium iodide, $N(C_2H_5)_4I.3\frac{1}{2}HgI_2$ and of $N(C_2H_5)_4I.N(C_2H_5)_2HgI$. M. Zipkin also obtained a double compound, $2N(C_2H_5)_4I.3HgI_2$, by heating a mixture of ethyl iodide and mercuric chloroamide for four months on a water-bath; and after six months' heating, $NH_4I.HgI_2$, together with a little ethylamine and ammonium chloride. S. Hajnoci and M. Löw have studied the action of *methyl iodide* on mercuric chloroamide, and obtained a mixture of $NH_4I.2HgI_2$ or $NH_4Hg_2I_5$, and of mercuric methylammino-iodide, $HgI_2.N(CH_3)_2$. H. Edhem-Bey found after five weeks' exposure with *chloroform*, mercuric chloroamide forms ammonium and mercuric chlorides, and carbon chloride. Similar results were observed with *iodoform*. R. Wagner found *amyl mercaptan*, $C_5H_{11}SH$, furnishes a white crystalline compound and mercuric diammino-chloride: $2Hg(NH_2)Cl + 2C_5H_{11}SH = HgCl_2.2NH_3 + (C_5H_{11})_2S_2Hg$, which when dried at 100° and distilled forms mercuric sulphide and amylamine hydrochloride $2(C_5H_{11})NH_2.HCl$. C. Kosmann studied the action of quinine sulphate on mercuric chloroamides.

According to H. Edhem-Bey, *sodium amalgam* attacks mercuric chloroamide with the evolution of ammonia by an exothermal reaction, the mixture becomes brown and then black, and the residue contains sodium chloride, yellow mercuric oxide, and mercury. Similar changes are observed with *alkali hydroxides*. R. J. Kane,

L. Pesci, and H. Gaudechon said that the chloroamide becomes yellow when treated at ordinary temp. with a soln. of potassium or *calcium hydroxide*, half the contained nitrogen is evolved as ammonia, and this fact has been cited in favour of C. F. Rammelsberg and L. Pesci's formula $\text{NH}_4\text{Cl}.\text{NHg}_2\text{Cl}$ against R. J. Kane's formula $\text{NH}_2.\text{Hg}.\text{Cl}$, but K. A. Hofmann and E. C. Marburg say that at 130° , the compound loses all its contained nitrogen, as ammonia, when heated with 20 per cent. potassium hydroxide.

There are some compounds which may be regarded as addition products of mercuric chloroamide. For example, N. A. E. Millon's⁴ $\text{NH}_2.\text{Hg}_2.\text{Cl}_3$ may be regarded as a double *mercuric chloride and chloroamide*, $\text{HgCl}_2.\text{Hg}(\text{NH}_2)\text{Cl}$; or,

or, according to E. C. Franklin, as a basic mixture, $3\text{HgCl}_2.\text{Hg}(\text{NH}_2)_2$; or, according to E. Balestra as a double dimercuriammonium hydrogen chloride. N. A. E. Millon made this compound by adding aqua ammonia to a large excess of a cold soln. of mercuric chloride; E. Balestra, by adding half as much dil. ammonia to a soln. of mercuric chloride as is needed to precipitate all the mercury; and D. Strömholm, by shaking undried mercuric chloroamide with a 0.5 per cent. soln. of ammonium chloride containing a large proportion of mercuric chloride. H. Gaudechon does not accept the existence of the compound $\text{HgCl}_2.\text{H}_2\text{NHgCl}$; but M. C. C. Holmes made it by heating infusible white precipitate for 1 to 2 hrs. at 100° with a soln. of 0.3 to 1.0 gm. of ammonium chloride in 100 c.c. of water nearly sat. with mercuric chloride. On cooling the filtered soln., a fine white powder separated. The white powder resembles mercuric chloroamide; and it is decomposed into mercuric and ammonium chlorides by washing with cold water. D. Strömholm obtained what he regarded as $2\text{HgCl}_2.4\text{N}_2\text{HHg}_3\text{Cl}.\text{H}_2\text{O}$, by shaking this compound with water; and it is stable in soln. containing a high proportion of mercuric chloride, and a small proportion of ammonium chloride, if but a small proportion of mercuric chloride or a large proportion of ammonium chloride be present, the compound is decomposed; and E. Balestra found that no ammonia is given off when it is treated with potash lye, but is given off copiously when treated with a soln. of ammonium bromide. When hydrogen sulphide acts on the compound in the presence of water, the latter becomes acidic owing to the formation of *mercuric diamminochloroamide*, $\text{HgCl}_2.\text{Hg}(\text{NH}_2)\text{Cl}.2\text{NH}_3$. According to G. André, crystals of this compound are formed when 20 grms. of yellow mercuric oxide are dissolved in a soln. of 100 grms. of ammonium chloride in 350 grms. of water, and enough dil. ammonia added until the soln. smells strongly. The washed precipitate is dried at 100° . K. Thümmel obtained a white precipitate of a double *mercuric oxychloroamide*, $\text{HgO}.\text{HgCl}_2.2\text{Hg}(\text{NH}_2)\text{Cl}$, by adding mercuric chloride to an excess of ammonium hydrogen carbonate; when slowly heated to 180° or 200° , it produces a red powder—possibly $2\text{HgCl}_2.\text{Hg}_3\text{N}_2$. K. Thümmel also obtained what he regarded as $3\text{HgO}.\text{HgCl}_2.2\text{Hg}(\text{NH}_2)\text{Cl}$, as a flocculent white precipitate by adding a mixed soln. of sodium and ammonium hydrogen carbonates to one of mercuric chloride.

Mercuric hydroxychloroamide, $\text{HgOH}-\text{NH}-\text{HgCl}$, or *mercuric imidohydroxychloroamide* or the *chloride of Millon's base*. It can also be regarded as *dimercuriammonium monoquoachloride*, $\text{Hg}:\text{N}.\text{HgCl}, \text{H}_2\text{O}$; or as *oxydimercuriammonium chloride*, $\text{O}:\text{Hg}_2:\text{NH}_2\text{Cl}$; or as *mercuric oxychloroamide*, $\text{Hg}(\text{NH}_2).\text{O}.\text{HgCl}$. R. J. Kane⁵ showed that mercuric chloroamide, $\text{Hg}(\text{NH}_2)\text{Cl}$, is hydrolyzed by water, forming mercuric hydroxychloroamide, $\text{HgOH}.\text{NH}.\text{HgCl}$, the chloride of Millon's base. D. Strömholm, and K. A. Hofmann and E. C. Marburg prepared this compound by digesting the chloroamide with water at $60^\circ-70^\circ$ for 12 hrs., and washing the product first with hot water, then with alcohol, and finally with ether; it is then dried to constant weight in vacuo. C. F. Rammelsberg, and L. Pesci prepared it by the action of dil. hydrochloric acid on Millon's base, or by the action of a cold

soln. of hydrochloric acid in alcohol. D. Strömholm also hydrolyzed mercuric chloroamide by dissolving 3 grms. of the salt in 70 c.c. of 25 per cent. hydrochloric acid, and filtering the soln. into 500 c.c. of normal sodium hydroxide, and allowing the mixture to stand for some days. R. J. Kane, T. Weyl, and H. Gaudechon also prepared the same compound by the hydrolysis of mercuric diammino-chloride; and E. Balestra hydrolyzed dimercuric dichloroimide, $(\text{HgCl})_2\text{NH}$ or $(\text{HgCl})_2\text{N.Hg.N}(\text{HgCl})_2$, with a dil. soln. of potassium hydroxide; N. A. E. Millon obtained mercuric hydroxychloroamide by the action of an excess of ammonia on mercuric chloride, and washing the precipitate with hot water; D. Strömholm added 20 c.c. of 8 per cent. ammonia to a soln. of 5 grms. of mercuric chloride in a litre of water, and allowed the mixture to stand with repeated agitation for 6 days at the temp. of the room. G. André used an analogous process. G. André also prepared this compound by dissolving 20 grms. of yellow mercuric oxide in a boiling soln. of 100 grms. of ammonium chloride in 350 grms. of water. The filtered soln. is to be treated with dil. ammonia until it smells strongly of the gas, the precipitate is filtered off, and a large excess of water added to the liquid. H. Gaudechon treated the oxychloride 3HgO.HgCl_2 , or an eq. mixture of the components, with ammonia; and C. Ullgren passed dried ammonia at 150° over the same oxychloride dried at 100° . H. Fürth made the same compound by the action of ammonium chloride on mercuric chloride acetamide, $\text{HgCl}_2.\text{CO}(\text{CH}_3)\text{NH}_2$.

Mercuric hydroxychloroamide is usually pale yellow or cream colour, but when pure it is a white powder; that obtained by the aid of potassium is always yellow. R. J. Kane reported that when heated, ammonia, nitrogen, and water are evolved and a sublimate of mercury and mercuric chloride is formed; while C. F. Rammelsberg noted that it loses nearly all its combined water at 200° ; D. Strömholm gives 120° . This compound is so stable, said H. Gaudechon, that the combined water cannot be separated without decomposition, for if a little water be expelled by heating it to 130° for 5–6 hrs., the product leaves a residue of mercury when extracted with a soln. of potassium cyanide. K. A. Hofmann and E. C. Marburg say that it is not altered by heating to 120° in a stream of ammonia, or when it is allowed to stand over sulphuric acid. R. J. Kane said it is sparingly soluble in water, and easily soluble in hydrochloric or nitric acid; while H. Gaudechon says it is decomposed by hydrochloric acid, forming mercuric and ammonium chlorides, and C. Ullgren that with hot conc. nitric acid it gives a nitrogen trioxide. D. Strömholm says it is in equilibrium with a 0.15 per cent. soln. of ammonium chloride: $\text{HgOH.NH.HgCl} + \text{NH}_4\text{Cl} \rightleftharpoons \text{H}_2\text{O} + 2\text{Hg}(\text{NH}_2)\text{Cl}$. L. Pesci found it gives off its nitrogen as ammonia when treated with ammonium bromide; C. F. Rammelsberg obtained similar results with boiling soln. of the alkali chlorides; and C. Ullgren obtained ammonia and mercuric sulphide, by treating it with a soln. of potassium sulphide. E. Balestra obtained mercuric sulphide and a neutral soln. of ammonium chloride by the action of hydrogen sulphide. R. J. Kane found that a boiling soln. of potassium hydroxide gave off no ammonia, and changed only the colour of the salt; E. Balestra confirmed this observation. F. A. Flückiger found that when rubbed up with iodine, mercurous iodide is formed at first, and after some time mercuric iodide; the change is faster if the mixture be warmed with water. M. Zipkin obtained a double salt of mercuric iodide and tetramethyl ammonium iodide by heating it with ethyl iodide for 8 hrs. in a sealed tube on a water-bath. C. F. Rammelsberg noted that a soln. of potassium iodide forms mercuric imidohydroxyiodide, and with an excess of potassium iodide there is a partial decomposition and some ammonia is evolved.

O. Schmieder⁶ reported the formation of two *mercuric oxyhydroxychloroamides* which E. C. Franklin formulated as containing $\text{HgO} : \text{HgOH.NH.HgCl}$ in the ratios 1:1 and 1:2, but which O. Schmieder regarded respectively as compounds $\text{NH}_2(\text{HgO.HgO.Hg})\text{Cl}$, and $\text{NH}_2(\text{Hg.O.Hg})\text{Cl.NH}_2(\text{HgOHgOHg})\text{Cl}$. The 1:2 compound was made by pouring a dilute hydrochloric acid soln. of hydrated mercuric diammino-sulphate, $\text{HgSO}_4.2\text{NH}_3.\text{H}_2\text{O}$, into an excess of dil. potassium hydroxide, and washing the product with hot water; when this substance is boiled with conc.

potash-lye, it forms the 1 : 1 compound. N. A. E. Millon claimed to have made a pale yellow powder of a double compound of *mercuric chloroamide* and *hydroxy-chloroamide*, which E. C. Franklin formulated $\text{Hg}(\text{NH}_2)\text{Cl} \cdot 2(\text{HgOH} \cdot \text{NH} \cdot \text{HgCl})$, by the prolonged washing of $\text{HgCl}_2 \cdot \text{Hg}(\text{NH}_2)\text{Cl}$ with water, and by the action of ammonia on a boiling soln. of mercuric chloride—for the latter process G. André recommended pouring 3 vols. of a soln. of 33·875 grms. of mercuric chloride in a litre of water into 2 vols. of a soln. of 4·25 grms. of ammonia in a litre of water; the precipitate remaining after decantation was shaken for 24 hrs. with four more volumes of the ammonia soln., and filtered. E. Balestra failed to prepare this compound by either of N. A. E. Millon's processes, and he regards the product as a mixture of $\text{NH}(\text{HgCl})_2$, i.e. $\text{NHg}_2\text{Cl} \cdot \text{HCl}$ with $2\text{NHg}_2\text{Cl} \cdot \text{HgCl}_2$. The alternative formula by G. André is $\text{Hg}(\text{NH}_2)\text{Cl} \cdot 2(\text{NH}_2\text{Hg} \cdot \text{O} \cdot \text{HgCl})$. G. André also claimed to have made the 1 : 1 and the 2 : 1 salts which E. C. Franklin formulates respectively $\text{Hg}(\text{NH}_2)\text{Cl} \cdot \text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$, and $2\text{Hg}(\text{NH}_2)\text{Cl} \cdot \text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$; the former compound by pouring 6 vols. of a soln. of 4·25 grms. of ammonia in a litre of water into one part of a soln. of 33·875 grms. of mercuric chloride in a litre, and, after standing some hours, washing and drying the precipitate at 110° . The 2 : 1 compound was made by treating one volume of the mercuric chloride with 240 vols. of the ammonia soln. in a similar manner. The 4 : 1 compound, which E. C. Franklin formulates $4\text{Hg}(\text{NH}_2)\text{Cl} \cdot \text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$, was made by N. A. E. Millon by pouring a boiling soln. of mercuric chloride into an excess of aqua ammonia, and washing thoroughly with cold water. E. Balestra regards it as the end-product obtained by thoroughly washing mercuric chloroamide with water.

Dimercuriammonium chloride, or *tetramercuriammonium chloride*, NHg_2Cl , probably has the constitution $\text{Hg} : \text{N} \cdot \text{HgCl}$, although E. C. Franklin⁷ said that it may be also regarded as a basic mixture of mercuric chloride and nitride, or *mercuric chloronitride*, $\text{HgCl}_2 \cdot \text{Hg}_3\text{N}_2$. According to H. Gaudechon, this compound has not been isolated, but its existence is made probable by the fact that the corresponding iodide and bromide have been obtained. G. André, K. A. Hofmann and E. C. Marburg, P. C. Ray, and H. Gaudechon believe that the alleged production of this compound is an error. The latter said :

I have tried to make NHg_2Cl , but all attempts—action of heat, decomposition of double salts, etc.—have not enabled me to isolate it. The impossibility of eliminating the water from the chloride of Millon's first base $\text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$, or $\text{NHg}_2\text{Cl} \cdot \text{H}_2\text{O}$, without decomposition led K. A. Hofmann and E. C. Marburg to infer that this compound possesses a constitution different from $\text{NHg}_2\text{Cl} \cdot \text{H}_2\text{O}$, assumed by C. F. Rammelsberg and L. Pesci.

T. Weyl claimed to have made dimercuriammonium chloride by treating $\text{Hg} : \text{N} \cdot \text{HgOH}$ —the second anhydride of Millon's base—with a cold alcoholic soln. of hydrogen chloride; and by the action of liquid ammonia on the oxychloride $3\text{HgO} \cdot \text{HgCl}_2$; C. F. Rammelsberg obtained it by heating the chloride of Millon's base to 200° ; by boiling fusible or infusible white precipitate with water or potash-lye; and by treating $\text{Hg} : \text{N} \cdot \text{HgCl}$ with the calculated quantity of hydrochloric acid; and H. Gerresheim, and C. F. Rammelsberg, by the action of sodium chloride soln. on $\text{Hg} : \text{N} \cdot \text{HgCl}$. T. Weyl says this compound is a yellow powder which at 300° decomposes suddenly into mercuric chloride, mercury, and nitrogen. It is not decomposed by boiling water; cold dilute hydrochloric acid dissolves it very slowly; cold potash-lye forms potassium chloride and a yellow powder which when washed with alcoholic ammonia and dried, explodes when rapidly heated. Boiling potash-lye was found by L. Pesci, and T. Weyl to decompose it completely, forming ammonia, and mercuric oxide and chloride; soln. of potassium chloride, said T. Weyl, act similarly. L. Pesci showed that an 8 per cent. soln. of ammonium chloride converts it at ordinary temp. into fusible white precipitate, $\text{HgCl}_2 \cdot 2\text{NH}_3$. H. Gaudechon reported the formation of four **dimercuriammonium amino-chlorides**, $\text{NHg}_2\text{Cl} \cdot n\text{NH}_3$, where n is $\frac{1}{2}$, $\frac{1}{3}$, 1, and 3. C. F. Rammelsberg's, L. Pesci's, and H. Gaudechon's formulæ for infusible and fusible white precipitates represent them as double compounds of dimercuriammonium chloride and ammonium

chloride respectively in the proportions 1 : 1 and 1 : 3, that is, $\text{NHg}_2\text{Cl} \cdot \text{NH}_4\text{Cl}$ and $\text{NHg}_2\text{Cl} \cdot 3\text{NH}_4\text{Cl}$ respectively.

H. Gaudechon said that the so-called *hydrates of dimercuriammonium chloride*, namely, $\text{NHg}_2\text{Cl} \cdot n\text{H}_2\text{O}$, where $n = \frac{1}{4}, \frac{1}{2},$ and 1, are not different stages in the hydration of this compound, but rather different condensation products, $(\text{NHg}_2\text{Cl})_n$, $(\text{NHg}_2\text{Cl})_{2n}$, and $(\text{NHg}_2\text{Cl})_{4n}$. While the compound $\text{NHg}_2\text{Cl} \cdot n\text{H}_2\text{O}$ is preferably regarded as $\text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$, the compound $\text{NHg}_2\text{Cl} \cdot \frac{1}{4}\text{H}_2\text{O}$ is said by H. Gaudechon to be formed by drying $\text{NHgCl} \cdot n\text{H}_2\text{O}$ at 100° ; and the compound $\text{NHg}_2\text{Cl} \cdot \frac{1}{2}\text{H}_2\text{O}$ was regarded by R. Kane and G. André as having the composition $\text{NHg}_2\text{Cl} \cdot \text{NH}_2\text{Hg} \cdot \text{O} \cdot \text{HgCl}$, while E. C. Franklin assumes it to be a double salt of *dimercuriammonium chloride*, and *mercuric chlorohydroxyamide*, with $\text{NHg}_2\text{Cl} : \text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$ in the proportions 1 : 1. G. André made this double salt by mixing 200 c.c. of $\frac{1}{8}N$ -mercuric chloride soln. with 150 c.c. of a $\frac{1}{2}N$ -potassium hydroxide, and then adding 100 c.c. of a $\frac{1}{2}N$ -ammonia—or 150 c.c. of $\frac{1}{8}N$ -ammonium chloride soln. The yellow colour disappears after shaking the mixture for half an hour; it is then filtered, washed with cold water, and dried at 110° . H. Gaudechon made it by the action of dil. hydrochloric acid on $\text{NHgOH} \cdot \text{H}_2\text{O}$; by dehydrating $\text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$ with liquid ammonia; and by boiling fusible or infusible white precipitate with water, or, according to L. Pesci, by treating them with a 20 per cent. soln. of potassium hydroxide or sodium carbonate. P. C. Ray hydrolyzed ammonium pentachlorodimercuriate, $\text{NH}_4\text{Hg}_2\text{Cl}_5$, or $\text{NH}_4\text{Cl} \cdot 2\text{HgCl}_2$, with dilute potash-lye, and J. Sen similarly hydrolyzed mercuric chloroamide. The product is a pale yellow powder which is very stable. According to H. Gaudechon, the heat of formation is 24.8 Cals., and the heat of hydration 2.0 Cals. P. C. Ray says it loses no appreciable quantity of water at 120° ; on further heating J. Sen found it to be decomposed into nitrogen, mercury, and mercurous chloride—a little of the nitrogen may be given off as ammonia. If allowed to stand for several days in contact with water at 15° , H. Gaudechon could detect no transformation into $\text{NHg}_2\text{Cl} \cdot \text{H}_2\text{O}$, nor indeed by heating to 100° for 100 hrs. G. André also prepared what E. C. Franklin formulated as the 1 : 2 double compound $\text{Hg}_2\text{NCl} \cdot 2(\text{HgOH} \cdot \text{NH} \cdot \text{HgCl})$, and G. André as $\text{Hg}_2\text{NCl} \cdot 2(\text{NH}_2\text{Hg} \cdot \text{O} \cdot \text{HgCl})$ or as $3\text{Hg}_2\text{NCl} \cdot 2\text{H}_2\text{O}$, by pouring 200 c.c. of $\frac{1}{8}N$ -mercuric chloride into 400 c.c. of ammonia, and washing the precipitate rapidly by decantation with a small quantity of water. The precipitate was then shaken for $1\frac{1}{2}$ hrs., filtered, washed, and dried at 110° . He also prepared the same compound by adding an ammoniacal soln. of potassium hydroxide into $\frac{1}{8}N$ -mercuric chloride soln.

G. André reported what may be regarded as triple compounds of mercuric chloroamide and hydroxychloroamide with dimercuriammonium chloride, $\text{Hg}(\text{NH}_2)\text{Cl} : \text{Hg}_2\text{NCl} : \text{HgOH} \cdot \text{NH} \cdot \text{HgCl}$ in the molecular proportions 1 : 1 : 1; 1 : 2 : 1, and 2 : 1 : 1.

Mercuric dichloroamide, $(\text{HgCl})_2\text{NH}$.—E. C. Franklin⁸ also suggests that this compound may be really a basic mixture of mercuric chloride, HgCl_2 , and mercuric imide, HgNH . E. Balestra regards it as a complex acid or double compound of hydrochloric acid and dimercuriammonium chloride, $\text{NHg}_2\text{Cl} \cdot \text{HCl}$, just as the compound $\text{HgCl}_2 \cdot \text{NH}_2\text{HgCl}$ can be regarded as $\text{NHg}_2\text{Cl} \cdot 2\text{HCl}$; and NH_4HgCl_5 or $\text{NH}_4\text{Cl} \cdot 2\text{HgCl}_2$, as $\text{NHg}_2\text{Cl} \cdot 4\text{HCl}$. E. Balestra made this compound by adding to 200 c.c. of a boiling 7 per cent. soln. of mercuric chloride, half as much ammonia as is necessary to make the soln. neutral to litmus. The amorphous yellow powder is dried in air; when suspended in water, it is decomposed by hydrogen sulphide, and the water acquires a strong acid reaction. It develops ammonia when digested with ammonium bromide, but not with potash-lye.

Mercuric tetrachloroamide, $(\text{HgCl})_2\text{N} \cdot \text{Hg} \cdot \text{N}(\text{HgCl})_2$.—E. C. Franklin considers the possibility of this substance being a basic mixture of mercuric chloride, HgCl_2 , and mercuric nitride, Hg_3N_2 , or *mercuric chloro-nitride*. It can be regarded as a double salt of dimercuriammonium and mercuric chloride, $2\text{NHg}_2\text{Cl} \cdot \text{HgCl}_2$; or of $\text{HgCl}_2(\text{Hg} : \text{N} \cdot \text{HgCl})_2$. E. Mitscherlich found it remaining in small red crystalline

plates resembling red mercuric oxide. When infusible white precipitate, NH_2HgCl , is carefully heated in a retort, immersed in a bath of fusible metal, until the ammonia is all driven off, and the mercuric monamminochloride, $\text{HgCl}_2 \cdot \text{NH}_3$, and mercuric chloride begin to sublime: $6\text{Hg}(\text{NH}_2)\text{Cl} = 3\text{NH}_3 + \text{Hg}(\text{NH}_2)\text{Cl}_2 + (\text{HgCl})_2 : \text{N.Hg.N} : (\text{HgCl})_2$. P. C. Ray made it as a yellow precipitate by adding potash-lye carefully, not in excess, to a boiling soln. of ammonium pentachlorodimercuriate, $\text{NH}_4\text{Cl} \cdot 2\text{HgCl}_2$. H. Gaudechon prepared it by the action of hydrochloric acid on the chloride of Millon's base; and by mixing a hot conc. soln. of mercuric chloride with an equi-molar quantity of ammonia, washing the precipitate free from chlorine, and drying at 100° . E. Mitscherlich says that this compound decomposes into nitrogen, mercury, and mercurous chloride when heated above the boiling point of mercury; it is scarcely affected by water at 18° , and it dissolves in boiling hydrochloric acid, forming ammonium and mercuric chlorides; boiling sulphuric acid decomposes it in an analogous manner; it is not dissolved or decomposed by boiling nitric acid, dil. sulphuric acid, or by alkalis. H. Gaudechon says that when treated with aqua ammonia, cold or hot, a mixture of $\text{Hg}(\text{NH}_2)\text{Cl}$ and HgCl.NH.HgOH is formed.

Mercuric trichloroamide, $\text{N}(\text{HgCl})_3$.—It will be observed that the mercuric chloroamides can be graphically represented by the formulæ:

H. Vittenet reported that when equal parts of ammonium and mercuric chlorides are dissolved in tap-water, there slowly forms a precipitate, which is at first white and has the composition $\text{N}(\text{HgCl})_2$, but on further standing gradually becomes yellow. The production of this substance was traced to the presence of acid carbonates in the water, and its formation was found to be inhibited by previously boiling the water. When the two salts are dissolved in distilled water to which sodium hydrogen carbonate or carbonate has been added, the precipitate formed is white and has the composition of a double salt with ammonium chloride, $\text{N}(\text{HgCl})_3 \cdot 3\text{NH}_4\text{Cl}$. H. Vittenet represents the reactions by the equations: $3\text{HgCl}_2 + 4\text{NH}_4\text{Cl} + 4\text{NaHCO}_3 = \text{N}(\text{HgCl})_3 \cdot 3\text{NH}_4\text{Cl} + 4\text{NaCl} + 4\text{CO}_2 + 4\text{H}_2\text{O}$; and $3\text{HgCl}_2 + 4\text{NH}_4\text{Cl} + 2\text{Na}_2\text{CO}_3 = \text{N}(\text{HgCl})_3 \cdot 3\text{NH}_4\text{Cl} + 4\text{NaCl} + 2\text{CO}_2 + 2\text{H}_2\text{O}$. The compound $\text{N}(\text{HgCl})_3 \cdot 3\text{NH}_4\text{Cl}$ gradually becomes yellow when washed with water; the final product is bright yellow, and has approximately the composition required for **mercuric dihydroxyhypochloroamide**, $\text{N}(\text{Hg.OH})_2 \cdot \text{Hg.OCl}$. **Mercuric hydroxydichloroamide**, $\text{N}(\text{HgCl})_2 \cdot \text{HgOH}$, is formed as an intermediate product, $2\text{N}(\text{HgCl})_3 + \text{O}_2 = 2\text{N}(\text{HgCl})_2 \cdot \text{HgOCl}$; and $\text{N}(\text{HgCl})_3 + \text{H}_2\text{O} = \text{HCl} + \text{HgOH.N}(\text{HgCl})_2$. The formation of these precipitates in soln. used in antiseptic baths leads to a diminution of efficiency, and it is suggested that in preparing these, the water should first be boiled or the ammonium chloride should be replaced by sodium chloride; with either of these precautions, no precipitation occurs.

§ 17. Hydroxylamine and Hydrazine Compounds of Mercuric Chloride

L. Crismer¹ has prepared chlorides of barium, zinc, cadmium, cobalt, and manganese with hydroxylamine of crystallization of the general formula $MCl_2 \cdot (NH_2OH)_2$, but W. Feldt failed to obtain a mercuric salt analogous with the sulphates of manganese, cobalt, and nickel prepared in conjunction with R. Uhlenhuth. In an attempt to prepare compounds with hydroxylamine analogous with

the aminomercuriates, W. F. C. Dresler and R. Stein found that hydroxylamine reduced mercuric oxide to free mercury; W. Lossen found that mercuric chloride was rapidly reduced; but M. Adams prepared several compounds of hydroxylamine with mercuric salts by varying the temperature and solvent.

Freshly precipitated mercurous chloride is very slightly soluble in hydroxylamine hydrochloride, but no combination has been observed; when mercurous chloride is boiled with hydroxylamine and methyl alcohol in a flask fitted with a reflux condenser, the mercurous salt is slowly reduced; the reduction proceeds much more slowly in the cold. The presence of hydroxylamine hydrochloride raises the solubility of mercuric chloride in water or in alcohol, and white crystals of **mercuric hydroxylamine hydrochloride**, $\text{HgCl}_2(\text{NH}_2\text{OH})\cdot\text{HCl}$, are obtained by mixing a mol each of mercuric chloride and hydroxylamine hydrochloride in as little water as possible, and evaporating the soln. over calcium chloride. The salt is so very soluble in alcohol and in water that it is difficult to purify; it is less soluble in ether. A mixed soln. of mercuric chloride and hydroxylamine hydrochloride in excess of the proportion 1 : 1, when evaporated, furnishes crystals of the former salt, and if less than this proportion be used, hydroxylamine hydrochloride separates out. If other salts are formed they dissociate on conc. and cannot be obtained in this way. The low solubility of hydroxylamine hydrochloride in ether is not favourable to the production of double salts with an ethereal soln. of mercuric chloride; and although the solubility of the hydrochloride is augmented if alcohol or ligroin be present, no definite double salt could be obtained.

If free hydroxylamine be present, the case is different, for whenever mercuric chloride is present in soln. with an excess of hydroxylamine and its hydrochloride, **dimercuric decahydroxylamine hydrochloride**, $2\text{HgCl}_2\cdot 5(\text{NH}_2\text{OH})_2\cdot\text{HCl}$, is formed. This salt is the most easily prepared of the mercuric hydroxylamine salts, and M. Adams indicates several modes of preparation—*e.g.* the action of an alcoholic soln. of hydroxylamine hydrochloride on freshly prepared mercuric oxide suspended in alcohol at about -10° ; etc. The salt is soluble in water at ordinary temp., and is gradually reduced to mercurous chloride; it is soluble in alcohol, ether, and hydrochloric acid. The presence of a trace of alkali hastens the decomposition—*e.g.* mercuric oxide at -10° slowly decomposes the salt. When aq. ammonia is added to the aq. soln. a white precipitate is formed which gradually blackens in the cold, rapidly when heated.

M. Adams prepared **mercuric dihydroxylamine chloride**, $\text{HgCl}_2(\text{NH}_2\text{OH})_2$, by adding a cold alcoholic soln. of hydroxylamine, drop by drop, with constant agitation, to a soln. of mercuric chloride in absolute alcohol cooled down to -10° , or by adding free hydroxylamine in a similar manner, to an alcoholic soln. of hydroxylamine hydrochloride with four times its weight of mercuric chloride. White microscopic crystals soon separate out; they are contaminated with mercurous chloride and combined hydroxylamine hydrochloride. The washed crystals are purified by dissolving them in absolute alcohol to which a trace of hydroxylamine hydrochloride has been added, and long white acicular crystals separate from the soln. The salt is fairly soluble in methyl or ethyl alcohol from which soln. it is precipitated by ether; it is insoluble in ether. On standing in absolute alcohol there is much reduction, the action is more rapid in warm soln. than in the cold. The salt is readily soluble in an aq. soln. of hydroxylamine hydrochloride, and an aq. soln. of the salt is much more stable if a little hydroxylamine hydrochloride is present—presumably a double salt is formed. Sodium hydroxide rapidly decomposes the salt; if ammonia be added to an alcoholic soln. or an aq. soln. mixed with hydroxylamine hydrochloride, a white precipitate is formed which becomes black on standing in the cold, or immediately on warming.

In the preceding preparation, if a mol of mercuric chloride with two of hydroxylamine hydrochloride be employed, the resulting crystals, when purified by recrystallization from methyl alcohol, have the composition **mercuric tetrahydroxylamine dihydrochloride**, $\text{HgCl}_2(\text{NH}_2\text{OH})_2(\text{NH}_2\text{OH}\cdot\text{HCl})_2$. If a mol each of mercuric and

hydroxylamine hydrochlorides be employed, crystals of **mercuric tetrahydroxylamine hydrochloride**, $\text{HgCl}_2(\text{NH}_2\text{OH})_4\text{HCl}$, are formed. Both salts are soluble in methyl or ethyl alcohol; they are unstable in aq. soln.; and in the presence of alkalis. The former salt appears to be the most stable of the mercuric hydroxylamine salts, and it can be recrystallized unchanged from methyl alcohol; the latter salt is largely reduced under similar conditions, furnishing mercuric chloride and mercuric dihydroxylamine chloride.

T. Curtius and F. Schrader² found that mercuric chloride is reduced by hydrazine dihydrochloride, forming a yellow precipitate which soon turns grey, and cannot be isolated. Hydrazine dihydrochloride precipitates mercurous chloride from soln. of mercurous nitrate. K. A. Hofmann and E. C. Marburg prepared hydrazine derivatives of mercuric chloride which they believe to be analogous with the mercuri-ammonium compounds. When mercuric chloride and hydrazine hydrate are brought together in soln. in alcohol and ether, **mercuric hydrazine chloride**, $\text{N}_2\text{H}_4\text{HgCl}_2$, is precipitated; it is moderately stable when dry, but unstable when moist, and decomposes rapidly when heated, but does not explode. When this compound is shaken with water, or when sodium acetate is added to the mixed aq. soln. of hydrazine sulphate and mercuric chloride, an unstable yellow **mercuric hydrazidochloride**, $\text{N}_2\text{H}_2\text{Hg}_2\text{Cl}_2$, is produced which explodes when heated or struck, and rapidly decomposes when moist, nitrogen being evolved and mercury and calomel left. It is readily soluble in hydrochloric acid, but always leaves a small residue of calomel. Alkalies decompose it rapidly. These two compounds appear to be strictly analogous to the fusible and infusible white precipitates, 2NH_3 , HgCl_2 , and NH_2HgCl . Lustrous tabular crystals of **mercuric hydrazine hydrochloride**, $\text{HgCl}_2\cdot\text{N}_2\text{H}_4\cdot\text{HCl}$, were made by treating the hydrazidochloride with chlorine in the presence of carbon tetrachloride; it is also formed from its components in the presence of an excess of mercuric chloride. The m.p. is 157° . T. Curtius and F. Schrader found that **mercuric dihydrazine hydrochloride**, $\text{HgCl}_2\cdot 2\text{N}_2\text{H}_4\cdot\text{HCl}$, is readily soluble, and may be recrystallized from water or alcohol. It forms well-developed six-sided prisms, which become opaque in the air, and melt at 178° without decomposing.

§ 18. Mercurous Bromide

There are two bromides of mercury—mercurous bromide, HgBr ; and mercuric bromide, HgBr_2 . A. J. Balard¹ found that mercury united with bromine at ordinary temp., and W. A. Shenstone showed that thoroughly dried bromine unites with dry mercury. The product is mercurous bromide if the mercury be in excess, and mercuric bromide if the bromine be in excess. M. Berthelot showed that at ordinary temp. hydrogen bromide and hydrogen gases slowly react with mercury, forming mercurous bromide; the action is faster if the temp. be raised, and, according to G. F. Bailey and G. J. Fowler, it is faster than with hydrogen chloride.

A. J. Balard precipitated mercurous bromide by adding potassium bromide to a soln. of mercurous nitrate in dil. nitric acid (1:100), and, add H. Saha and K. N. Choudhuri, the precipitate is first washed by decantation with light excluded, then washed on a filter, and dried over calcium chloride. R. Varet dried the

precipitate at 105°. O. Henry used other soluble bromides in place of the potassium salt. A. Stroman prepared the same salt by adding bromine, bromine water, or an alcoholic soln. of bromine to a soln. of mercurous nitrate. C. Löwig prepared mercurous bromide by sublimation from a mixture of a gram-atom of mercury, and a mol of mercuric bromide. According to A. Lottermoser, the preparation and properties of colloidal mercurous bromide resemble those for mercurous chloride.

The salt prepared by A. J. Balard's process is a white powder resembling calomel; that prepared by C. Löwig's process is a white fibrous mass; I. Guareschi obtained the salt by sublimation in small colourless crystals; and A. Stroman said that white tetragonal plates can be obtained by cooling a hot soln. of the salt in mercurous nitrate. C. J. B. Karsten found the sp. gr. to be 7.307. O. Henry noted that the white salt becomes yellow when heated, and the white colour is restored on cooling; the salt also melts—according to T. Carneiley—at about 405°, and, according to C. Löwig, it volatilizes without decomposition at a red heat. A. Stroman noted that volatilization occurs at 340° to 350°. E. Beckmann found the lowering of the f.p. of mercuric bromide by the addition of mercurous bromide agreed with the formula Hg_2Br_2 . E. Mitscherlich's value for the vapour density, air unity, is 10.14, the corresponding mol. wt. is near that required for HgBr , or, as in the analogous case of mercuric chloride, with that required for partial or complete dissociation into $\text{HgBr}_2 + \text{Hg}$. J. Thomsen's value² for the heat of formation from its elements is $(2\text{Hg}, \text{Br}_2)$, 68.29 Cals.; M. Berthelot gives $\text{Hg}_{\text{solid}} + \text{Br}_{\text{solid}} = \text{HgBr}_{\text{solid}} + 35$ Cals.; and R. Varet, $2\text{Hg}_{\text{liq.}} + \text{Br}_{2\text{liq.}} = \text{Hg}_2\text{Br}_{2\text{solid}} + 49.1$ Cals.; $2\text{Hg}_{\text{liq.}} + \text{Br}_{2\text{gas}} = \text{Hg}_2\text{Br}_{2\text{solid}} + 56.4$ Cals. J. Thomsen also gives $(\text{Hg}_2\text{O}, 2\text{HBr}_{\text{gas}}) = 77.57$ Cals.; and $(2\text{HgNO}_{3\text{aq.}}, 2\text{KBr}_{\text{aq.}}) = 31.94$ Cals. R. Varet gives $\text{Hg}_2\text{O} + 2\text{HBr}_{\text{aq.}} = \text{Hg}_2\text{Br}_{2\text{solid}} + \text{H}_2\text{O} + 38.76$ Cals.; and $\text{HgBr}_{2\text{solid}} + \text{Hg}_{\text{liq.}} = \text{Hg}_2\text{Br}_{2\text{solid}} + 8.5$ Cals. The free energy of formation at 18°, calculated by M. de K. Thompson, is 42.8 Cals., and the total energy, 49 Cals. F. Braun obtained a transformation of 41 to 46 per cent. of the thermal into electrical energy with gaseous or liquid bromine. According to M. Berthelot, the displacement of the bromine by chlorine develops 5.6 Cals.

According to O. Wolff,³ the vapour of mercurous bromide has an orange fluorescence in ultra-violet light; and, according to J. A. Wilkinson, the vapour is luminescent. A. Stroman found mercurous bromide to be far less sensitive to light than mercurous iodide. C. Fritsch has measured the conductivity of pressed plates of mercurous bromide. According to H. M. Goodwin, the electromotive force of the cell $\text{Hg} | \text{Hg}_2\text{Br}_2, \frac{1}{10}N\text{-KBr} | \frac{1}{10}N\text{-KCl}, \text{Hg}_2\text{Cl}_2 | \text{Hg}$ is 0.1338 volt at 17°; according to S. Bugarsky, for $\text{Hg} | \text{Hg}_2\text{Br}_2, \frac{1}{100}N\text{-KBr} | N\text{-KNO}_3 | \frac{1}{10}N\text{-KCl}, \text{Hg}_2\text{Cl}_2 | \text{Hg}$ the e.m.f. is $\epsilon = 0.2149$ volt at 43.3°; 0.1285 volt at 18°; and 0.1311 at 0°; and $d\epsilon/d\theta = -0.000144$. The calculated free energy is 297 cals., the bound energy 964 cals., and the total energy 3935 cals.—the observed heat of the reaction is 4010 cals. For $\text{Hg} | \text{Hg}_2\text{Br}_2, \frac{1}{100}N\text{-KBr} | N\text{-KC}_2\text{H}_3\text{O}_2 | N\text{-KC}_2\text{H}_3\text{O}_2, \text{Hg}_2(\text{C}_2\text{H}_3\text{O}_2)_2 | \text{Hg}$ the e.m.f. is $\epsilon = 0.2474$ volt at 18.5°; and 0.2667 volt at 0°, and $d\epsilon/d\theta = -0.00104$. The calculated free energy is 5717 cals., the bound energy 6906 cals., the total energy 12,620 cals.—the observed heat of the reaction is 1200 cals. According to R. Behrend, a soln. of mercurous bromide in $\frac{1}{10}N\text{-KBr}$ contains a milligram of Hg-ions per 1300 litres. On the inexact assumption that the whole of the dissolved mercury is present as Hg^{++} -ions, R. Abegg calculated from the measurements of C. Immerwahr and F. Jander, that soln. of mercurous bromide in potassium bromide of conc. N contain complexes of conc. C , and the ratios of the conc. of the complex to the free ions is K :

N	.	.	.	1.0	1.5	2.0	3.0
C	.	.	.	0.00805	0.0176	0.0343	0.0783
K	.	.	.	0.00805	0.0119	0.0172	0.0268

Mercurous bromide is odourless and tasteless. It was formerly considered to be insoluble in water, but more refined measurements have shown M. S. Sherrill⁴

that a litre of water dissolves 7×10^{-8} gm. per litre; G. Bodländer, 9.1×10^{-7} ; M. de K. Thompson, 1.4×10^{-7} ; and L. Rolla, 3×10^{-7} . As in the analogous case of mercurous chloride, mercurous bromide is slowly converted by water into mercuric bromide. According to R. Abegg, the conc. of the mercuric chloride in a sat. soln. of mercurous chloride is 2.4×10^{-6} mols per litre. A. Mailfert said that ozone converts mercurous bromide into mercuric bromide and oxybromide. According to T. Fischer and H. von Wartenberg, if a mixture of mercuric oxide, mercurous bromide, and water be heated in a sealed tube for 48 hrs. at 180° , and the unchanged mercuric oxide and mercurous bromide be removed by levigation, dark red rhombic plates of **mercurous oxybromide** are formed, $\text{HgO} \cdot \text{HgBr}$, and they behave towards alkalis and acids like a mixture of the two components. According to I. Guareschi, when a dry mixture of iodine and mercurous bromide is heated bromine and mercuric iodide are formed; but with the gradual addition of iodine to mercurous bromide, mercuric bromo-iodide is formed. According to A. Stroman, dil. or hot fuming hydrochloric acid blackens mercurous bromide owing to the separation of mercury, mercuric chloride passes into soln. According to L. Mailhe, the action of alkali chlorides on mercurous bromide resembles their effect on mercurous chloride. A. Ditte noted that mercurous bromide is decomposed by a conc. soln. of potassium cyanide or potassium iodide, forming a double salt and mercury. C. Löwig found that a boiling soln. of ammonium chloride or bromide decomposes mercurous bromide, forming the mercuric salt and mercury, but a cold soln. of ammonium chloride was reported by G. C. Wittstein to have no perceptible action. G. C. Wittstein also found that a cold soln. of ammonium carbonate or succinate has no appreciable action, while a hot soln. easily dissolves mercurous bromide, leaving behind a grey powder which is presumably metallic mercury; the same observer found that mercurous bromide is not perceptibly soluble in cold or boiling soln. of ammonium sulphate or nitrate. A. Stroman found that fuming nitric acid of sp. gr. 1.42 dissolves mercurous bromide after a prolonged heating; and it is completely dissolved by hot conc. sulphuric acid with the evolution of sulphur dioxide. Alkali hydroxides were found by C. Löwig to yield potassium bromide and mercurous oxide. The action of hydrocyanic acid on mercurous bromide, says E. Esteve, resembles its action on mercurous chloride. I. Guareschi observed no evolution of bromine when mercurous bromide is heated with 25 to 50 per cent. soln. of chromic acid. A. Naumann found mercurous bromide to be insoluble in benzonitrile. C. Löwig found that when mercurous bromide is heated with phosphorus, mercurous bromide is converted into phosphorous bromide, and mercury phosphide. According to C. F. Rammelsberg, when mercurous bromide is treated with cold aqua ammonia, and washed with water containing ammonia, it leaves a grey powder which contains globules of metallic mercury, and when heated yields a sublimate of mercury and of mercurous and mercuric bromides. According to A. Stroman, some ammonium bromide is formed at the same time, and, according to H. Saha and K. N. Choudhuri, the black residue is a mixture of finely divided mercury and of $\text{HgO} \cdot \text{NH}_2\text{HgBr} \cdot 2\text{H}_2\text{O}$ —dihydrated mercuric oxybromide. J. G. F. Druce formulated the reaction $2\text{NH}_4\text{OH} + \text{Hg}_2\text{Br}_2 = \text{NH}_2\text{HgBr} + \text{Hg} + \text{NH}_4\text{Br} + 2\text{H}_2\text{O}$.

§ 19. Mercuric Bromide

This compound was formed by A. J. Balard in 1826, by the action of an excess of bromine on mercury. C. W. Easley and B. F. Braun¹ conducted the process by passing a stream of purified dry nitrogen through an apparatus resembling that depicted in Fig. 22, after purified mercury has been introduced into the bulb by

FIG. 22.—The Preparation of Mercuric Bromide—C. W. Easley and B. F. Braun.

means of a funnel through the tubular *T*. When the air was expelled, the nitrogen was passed through liquid bromine before it entered the apparatus. The bulb was heated to 300°, the mercury in the bulb was converted into the bromide and sublimed into the receiver *R*, which was kept at a temp. of 235°. Nitrogen alone was passed through the apparatus during the sublimation. The heating was done by means of air ovens with asbestos walls. Beautiful needle-like crystals of mercuric bromide collected in the receiver.

C. Löwig, L. Larine, and W. Reinders prepared this same compound by the action of an excess of hot bromine water on mercury; T. Hjortdahl used alcohol in place of water, and J. Schröder used pyridine. Bromine was added so long as the supernatant liquor was decolorized, the excess of bromine was boiled off, and the filtered liquid evaporated for crystallization. W. L. Hardin sublimed the thoroughly dried crystals from a porcelain crucible into a glass tube.

C. Löwig made the same salt by the action of hot hydrobromic acid on mercuric oxide; and by sublimation from a mixture of mercuric sulphate and potassium bromide—O. Henry says the product always contains some mercurous bromide. C. Löwig also evaporated a mixed soln. of mercuric nitrate and potassium bromide so long as mercuric bromide crystallized out and purified the product by soln. in alcohol; and W. Sievers agitated an excess of bromine with a soln. of mercuric nitrate of sp. gr. 1.197: $\text{Hg}(\text{NO}_3)_2 + 2\text{Br}_2 + 2\text{H}_2\text{O} = \text{HgBr}_2 + 2\text{HOBr} + 2\text{HNO}_3$; the product was dissolved in a hot soln. of mercuric nitrate of the same sp. gr., the soln. was cooled, and the crystals washed first with water acidified with nitric acid, then with water, and finally dried. R. Wagner made this salt by the action of bromine water or of a soln. of bromine in hydrochloric acid on mercuric sulphide. A. Lottermoser prepared colloidal mercuric bromide like he prepared colloidal mercuric chloride.

The properties of mercuric bromide.—The crystals of mercuric bromide obtained from aq. soln. are lustrous white plates; and from alcoholic soln. white

needles. According to W. J. Luczizky,² the rhombic bipyramidal crystals have the axial ratios $a:b:c=0.6826:1:1.7953$; these crystals are not isomorphous with those of mercuric chloride, and therefore a second rhombic modification isomorphous with mercuric chloride is assumed to exist. This was confirmed by W. J. Luczizky, who obtained from alcoholic soln. the rhombic form of mercuric bromide. The ordinary form of mercuric bromide is isomorphous with the yellow form of mercuric iodide which is stable at the higher temp. Isomorphous mixtures of these two salts are readily formed, and the combination $\text{HgI}_2 \cdot \text{HgBr}_2$, or HgIBr , is particularly stable, and was assumed by A. Oppenheim to be a compound. J. S. van Nest, therefore, assumed that mercuric bromide is trimorphous, and that the third modification is isomorphous with the low temp. tetragonal form of mercuric iodide—*vide* Fig. 25 and the bromochlorides—but W. Reinders could not find any sign of a transition point at temp. down to -83.5° .

Numbers ranging from F. W. Clarke's 5.7379 (18°) to C. J. B. Karsten's 5.9202 have been published for the **specific gravity** of mercuric bromide. The mean of three determinations by J. S. van Nest is 6.064 ± 0.05 (20°), and W. Orloff's value for the **molecular volume** is 62.69 ; W. Biltz gave 59.4 assuming the sp. gr. to be 6.064 . According to K. Beck, the sp. gr. of the molten salt (water at 18° unity) is 5.26 at 240° , 5.24 at 258° , and for θ° between 240° and 340° E. B. R. Prideaux gives for the sp. gr. $5.116-0.00338(\theta-240)$. According to E. B. R. Prideaux, 100 vols. of the elements mercury and bromine, $\text{Hg} + \text{Br}_2$, on combination at 760 mm. become 107.4 vols.; and the sp. gr. at 200 mm. press. 5.037 falls to 4.840 at 860 mm., and to 4.821 at 860 mm. O. Grottrian found the sp. gr. of soln. with 0.223 per cent. of the salt is 1.0007 (17.99°), and 1.0001 (20.87°), and for 0.422 per cent. soln. 1.0025 (18.19°) and 1.0020 (20.40°). The **viscosities** of the molten salt were found by K. Beck to be 3.698 (240°), 3.321 (247°), and 2.208 (258°), when water at 25° is unity.

The reported numbers for the **melting point** vary from the 222° of J. S. van Nest⁴ the 222° – 223° of A. Oppenheim and to the 244° of T. Carnelley. F. M. G. Johnson found a break in the vap. press. curve corresponding with the m.p. 236° , which may also be regarded as the best representative value of determinations by E. Beckmann, W. Reinders, K. Beck, P. Niggli, and C. Sandonnini. F. M. G. Johnson gives 318° (760 mm.) for the **boiling point**; T. Carnelley and W. Hampe give 319° ; and F. Freyer and V. Meyer, 335° . As with mercuric chloride, E. Esteve noted that some salt is lost by volatilization during the evaporation of an aq. soln. on a water-bath and drying at 100° . A. J. Balard, and C. Löwig noted that mercuric bromide melts and is volatile, and W. Sievers added that it does not simultaneously decompose. H. Arctowsky found it to be volatile even at ordinary temp., and that after five hours' heating it lost 0.0101 grm. at 79.5° ; 0.0182 grm. at 105° ; and 0.0732 grm. at 126.5° . O. Sulc found the finely powdered salt lost 4.1 per cent. in weight at 101.5° . The **vapour pressure** of mercuric bromide, p mm. of mercury, has been measured by F. M. G. Johnson, E. B. R. Prideaux:

	162°	206°	229°	233°	238°	247°	255°	290°	318.5°
p	3	29	73	88	106	136	174	413	764

There is a break at the m.p., 236° , and at the b.p. E. Wiedemann, K. Stelzner, and G. Niederschulte give 0.045 mm. at 90° ; 0.18 mm. at 110° ; 0.72 mm. at 130° ; and 2.30 mm. at 150° . The **heat of vaporization** calculated by Clausius' formula is 14.24 cal., between 760 mm. and 800 mm. **Trouton's constant** is $Q/T=24.13$; and W. Ramsay and S. Young's ratio $T_1/T_2=1.043$ (750 to 450 mm.). E. Beckmann gave for the **latent heat of fusion**, 13.9 Cals. per gram. The **critical temperature** was found by L. Rotinjanz and W. Suchodsky to be 1011° K. in agreement with the value 1013° K. calculated from T. E. Thorpe and A. W. Rucker's formula. C. M. Guldberg's ratio $T_b/T_c=0.587$, where T_b denotes the b.p. and T_c the critical temp. in absolute degrees. H. Rassow gave 738° for the critical temp. M. Prud'homme, and E. van Aubel studied the relation between the critical temp., the b.p., and the m.p. According to E. Mitscherlich,

the **vapour density** is 12.16 (air unity) or 351 ($H_2=2$), when the theoretical value for $HgBr_2$ is 350. V. Borelli found the mol. wt. calculated from the lowering of the f.p. of water is 370, corresponding with $HgBr_2$ (360); M. Hamers, from the raising of the b.p. of soln. in ethyl acetate, found 345.7; H. Steiner, in methyl acetate, 293.4 to 343.4—representing a possible ionization of 12.5 per cent. or a possible reaction with the solvent; A. Werner and M. Stephani, in ethyl sulphide, 352; and J. Schröder, in pyridine, 418. P. Walden and M. Centnerszwer said that the calculated mol. wt. in dil. pyridine soln. is normal and increases with increasing conc. E. Beckmann found mercurous bromide has a mol. wt. agreeing with Hg_2Br_2 in fused mercuric bromide. F. Olivari measured the cryoscopic constants of mercuric bromide.

R. Varet⁵ estimates the **heat of formation** of mercuric bromide from the liquid elements to be 40.6 to 40.7 Cals., and from liquid mercury and gaseous bromine, 47.9 Cals.; J. Thomsen gives 50.55 Cals. (bromine liquid); and W. Nernst, 40.5 Cals. The **free energy** of formation from the ions is 23.52 cals., according to M. S. Sherrill; and M. de K. Thompson gave -37,300 cals. M. Berthelot gives ($HgBr$, Br_{solid}), 17.6 Cals.; and for the action of hot aq. hydrobromic acid on HgO , 26.4 Cals.; 23.0 Cals. in soln.; and for a soln. of one eq. of $HgBr$ in 40 litres at 12°, $2HBr + HgO$ (precipitated), 27.4 Cals. for $HgBr$ dissolved, and 30.8 Cals. for crystalline $HgBr_2$. M. Berthelot gives for the heat of soln. -3.4 Cals.

J. A. Wilkinson⁶ said that the vapour of mercuric bromide has an orange **fluorescence**. B. O. Peirce⁷ found the **emission spectrum** of mercuric bromide gave a band with a mid-point near 5000. C. Sheard and C. S. Morris found a continuous spectral band with mercuric bromide between 5075 and 4912. The **magnetic susceptibility** was found by S. Meyer to be 0.24×10^{-6} units of mass, and 0.15×10^{-6} units of vol. C. Fritsch⁸ measured the **electrical conductivity** of a pressed plate. W. Hampe says that melted mercuric bromide conducts better than mercuric chloride under similar conditions; the decomposition is not apparent, but there is a feeble polarization current. The sp. electrical conductivity in soln. of molten aluminium bromide at 99.5° rises from 0.01×10^{-5} with 1.38 per cent. soln. to 0.88×10^{-5} with 5.52 per cent. soln.; 41.89×10^{-5} with 8.14 per cent. soln.; and to 979.9×10^{-5} with 27.15 per cent. soln.

O. Grotrian measured the sp. electrical conductivities and found that aq. soln. with 0.223 per cent. of mercuric bromide at 18.09° and 25.92° had the respective sp. conductivities 0.15×10^{-8} and 0.19×10^{-8} ; and a 0.422 per cent. soln. at 18.01° and 25.94°, the respective sp. conductivities 0.24×10^{-8} and 0.30×10^{-8} . H. Ley and H. Kissel found the mol. conductivity of a soln. with a mol of the salt in 128 litres of water to be 1.3, and they add that the only compounds of bivalent mercury which show a tendency to ionization are those in which the metal is directly united with oxygen—thus, the mol. conductivities of the chloride and bromide are low, while the conductivity of the cyanide is even lower. According to H. N. Morse, the ionization constants are: $[Hg^{++}][Br'] = 0.4 \times 10^{-9} [HgBr]$; $[HgBr][Br'] = 5.0 \times 10^{-9} [HgBr_2]$; $[Hg^{++}][Br']^2 = 2.0 \times 10^{-18} [HgBr_2]$; and $[Hg^{++}][HgBr_2] = 0.08 [H_2Br]^2$. M. S. Sherrill gives for the complexes $[HgBr_4''] = 4.3 \times 10^{21} [Hg^{++}][Br']^4$; and $[HgBr_4''] = 2.8 \times 10^4 [HgBr_2][Br']^2$; and for the conc. of $HgBr_2$, 1.7×10^{-2} ; $[HgBr]$, and $[Br']$, 0.9×10^{-5} ; for $[Hg^{++}]$, 0.9×10^{-9} ; and for $[HgBr_4'']$, 2.8×10^{-8} . H. N. Morse measured the **transport numbers**. According to W. Matthies, the **glow discharge** in the vapour has a stronger cathode fall than with the vapour of mercuric chloride.

J. L. Lassaigne⁹ found the **solubility** of mercuric bromide to be 1.05 per cent. at 9°, and 16.7 to 25 per cent. in boiling water. L. Larine gives the solubility as about 0.8 per cent. at ordinary temp., and 8 to 9 per cent. at 100°. W. Herz and W. Paul say that at 25°, water dissolves 0.017 mol per litre—a similar result was obtained by F. Jander, M. S. Sherrill, and R. Abegg. According to H. N. Morse, at ordinary temp. a litre of water dissolves about 4 grms. of the salt, and, according to H. Gaudechon, 5 to 6 grms. A. Vicario said that if a hot soln. be cooled, more mercury will be present than if prepared cold, because boiling water decomposes

mercuric bromide into hydrobromic acid and a yellow oxybromide, and mercuric bromide is more soluble in a dil. soln. of hydrobromic acid than in water. C. Löwig also noted the increased solubility of the salt in hydrochloric or hydriodic acid; F. Jander made a similar observation with respect to soln. of sodium or potassium bromide—if S denotes the solubility of mercuric bromide in water, at 25° , and S_0 the solubility in soln. of alkali chloride containing C mols per litre :

C	0.1	0.5	1.0	2.0	3.0	4.0
$S-S_0(\text{KCl})$	0.071	0.342	0.691	1.390	2.079	2.322
$S-S_0(\text{NaCl})$	0.0697	0.398	0.798	—	1.864	—

It is assumed that the complexes KHgBr_3 and NaHgBr_3 are respectively formed—*q.v.* R. Abegg calculated the equilibrium constants for soln. of these complexes. M. S. Sherrill found that additions of from a half to one mol of potassium bromide raised the f.p. of soln. of mercuric bromide up to a maximum, and the further additions had very little effect on the f.p. of the soln. up to saturation. These phenomena are taken to mean that anionic complexes HgBr_4^- are at first formed, and this is later followed by the addition of more bromide to form a higher complex $\text{Hg}_2\text{Br}_6^{2-}$. R. Varet further added that the heat of combination of mercuric bromide with the bromides of other metals is approximately of the same order of magnitude for the same series of double salts. W. Herz and W. Paul obtained confirmatory results with soln. of bromine in mercuric bromide.

A. J. Balard¹⁰ found mercuric bromide is readily soluble in *alcohol*, but not so easily soluble as in *ether*. W. Reinders found this salt to be more soluble than the corresponding iodide; at 0° , alcohol dissolves 13.05 to 13.33 per cent. of mercuric bromide; 16.53 per cent. at 25° ; and 22.63 per cent. at 50° ; and according to W. Hampe, 9.58 grms. of the salt in 100 c.c. of alcohol at ordinary temp., and 12.62 grms. at the b.p. W. Hampe also measured the electrical conductivity of alcoholic and ethereal soln. W. Herz and G. Anders measured the solubility of mercuric bromide in mixtures of *methyl* or *ethyl alcohol* and water at 25° , and found the solubility to increase with increasing proportions of alcohol. W. Herz and F. Kuhn measured the solubilities, sp. gr., and viscosities of mercuric bromide in mixtures of methyl and ethyl alcohols; *methyl* and *propyl alcohols*; and in mixtures of ethyl and propyl alcohols. M. Dukelsky, also, measured the solubility in mixtures of ethyl alcohol and *benzene*. A. J. Balard noted that mercuric bromide is very soluble in ether, and W. Hampe gave the solubility as 0.567 grm. of HgBr_2 in a cold soln. of dry ether, and 3.2 grms. in a hot soln. W. Reinders noted that mercuric bromide is more soluble than the iodide in *acetone*—34.58 per cent. at 25° . J. Schröder, H. Steiner, F. Bezold, and A. Naumann found mercuric bromide to be soluble in *methyl acetate*—at 18° , 100 grms. of methyl acetate dissolve 21.93 grms. of mercuric bromide; and 24 grms. of the salt in 100 c.c. of the boiling liquid. A. Naumann and M. Hamers measured the solubility of mercuric bromide in *ethyl acetate*, and found at 18° , 100 grms. of ethyl acetate dissolve 13.05 grms. of mercuric bromide; and W. Herz and G. Anders measured the solubility in mixtures of ethyl acetate and water. W. Reinders found mercuric bromide to be more soluble than the iodide in *diethyl oxalate*. J. H. Mathews found mercuric bromide to be soluble in *allyl mustard oil* and he measured the electrical conductivity of the soln.; A. Werner, in *ethyl sulphide*; L. Mascarelli and M. Ascoli, in *nitrobenzene*, *nitrotoluene*, *p-nitroanisole*, and in *α -nitronaphthalene*. O. Sulc found that between 18° and 20° 100 grms. of *chloroform* dissolved 0.126 grm. of mercuric bromide; of *carbon tetrachloride*, 0.003 grm.; of *bromoform*, 0.679 grm.; of *ethyl bromide*, 2.31 grms.; of *ethylene dibromide*, 2.34 grms. C. Mehn noted the solubility of mercuric bromide in *benzene*, and M. S. Sherrill found a litre of benzene dissolved 0.0194 mol of the salt; M. Dukelsky, as indicated above, measured the solubility in mixtures of ethyl alcohol and benzene. M. S. Sherrill also measured the partition coeff. of the salt between water or potassium bromide soln. and benzene free from thiophene. H. N. Morse measured the partition coeff. between *toluene* and water, and between water and $\frac{1}{10}\text{N-Hg}(\text{NO}_3)_2$, J. Schröder and A. Naumann measured the solubility in *pyridine*. A. Naumann and F. Becker found it is soluble in *benzonitrile*. H. Arcetowsky found that, at -10° , *carbon disulphide* dissolves 0.049 per cent. of mercuric bromide; at 0° , 0.087 per cent.; at 10° , 0.122 per cent.; at 20° , 0.187 per cent.; and at 30° , 0.274 per cent.

For the solubility in soln. of the bromides of the alkalis and alkaline earths, *vide infra*. H. N. Morse found a litre of $\frac{1}{10}\text{N-mercuric nitrate}$ dissolves 20 grms. of mercuric bromide. W. A. Isbekoff measured the solubility in soln. of *aluminium bromide*. P. Niggli measured the solubility of mercuric bromide in liquid *sulphur dioxide*, and found at 159.4° , a 1.5 per cent. solubility. W. Herz and W. Paul

found the solubility of mercuric bromide in *bromine water* increased with increasing amounts of bromine, and they found indications of the formation of **mercuric perbromide**, HgBr_4 .

M. Berthelot¹¹ exposed moist and also dry purified mercuric bromide to **sunlight** in a sealed tube without noticing any decomposition, and he added that the decomposition which is observed with some pharmaceutical preparations is produced by the **organic matter** which is present. C. Löwig found that aq. soln., when exposed to sunlight, deposited mercurous bromide. W. Reinders observed that some decomposition occurred during the drying of the salt between 70° and 80° , for a specimen became grey, while a sample crystallized from alcohol showed a similar change at 60° . According to M. Kohn and A. Ostersetzter, the mercuric halides are reduced by **hydrogen peroxide** in alkaline soln. or by sodium peroxide, with the precipitation of mercury.

M. Berthelot found that **chlorine** displaced bromine from the dry salt with the evolution of 5.4 Cals., and in soln., 6.0 Cals., while F. Gramp observed no action with iodine with or without water; M. C. Schuyten said that in the presence of an excess of salt, the halogen in mercuric chloride, bromide, or iodide can be replaced by the other halogens except in the action of **iodine** on mercuric bromide, which displaces no bromine. C. F. Rammelsberg noted that **sodium hypochlorite** gave a precipitate of mercuric oxychloride with soln. of mercuric bromide; and, according to A. J. Balard, with **hypochlorous acid**, chlorine and bromine are evolved, and mercuric chloride and bromate are formed.

A. J. Balard said that when mercuric bromide is heated with conc. **sulphuric acid**, bromine is evolved; while H. Rose said this is not the case. G. Viard found the addition of an excess of sulphuric acid to a soln. of the salt, precipitated mercuric bromide. The behaviour of **hydrogen sulphide** on an aq. soln. resembles its action on an aq. soln. of the chloride; with soln. of the bromide in methyl acetate, F. Bezold and A. Naumann obtained a white precipitate of $\text{HgBr}_2 \cdot 2\text{HgS}$, which is blackened by light; **ammonium sulphide** in the same soln. gives mercuric sulphide; M. Hamers and A. Naumann also obtained a white precipitate of $\text{HgBr}_2 \cdot 2\text{HgS}$ with hydrogen sulphide in ethyl acetate soln.; and in pyridine soln., J. Schröder found red mercuric sulphide to be precipitated. According to G. Franceschi, when a few drops of pure alcoholic soln. of hydrogen sulphide are added to an alcoholic soln. of mercuric bromide free from the mercurous salt, a white turbidity is produced, and afterwards mercurous bromide is precipitated—presumably: $2\text{HgBr}_2 + \text{H}_2\text{S} = \text{S} + 2\text{HBr} + 2\text{HgBr}$; if a larger quantity of the hydrogen sulphide soln. is used, but not an excess, a canary-yellow precipitate of $2\text{HgS} \cdot \text{HgBr}$, *i.e.* $\text{Hg}(\text{SHgBr})_2$, is formed, presumably: $\text{H}_2\text{S} + 6\text{HgBr} + 3\text{S} = 2\text{HBr} + 2(\text{HgBr}_2 \cdot 2\text{HgS})$; while if the hydrogen sulphide soln. be in excess, a black precipitate of mercuric sulphide is produced—presumably: $\text{H}_2\text{S} + 2\text{HgS} \cdot \text{HgBr}_2 = 3\text{HgS} + 2\text{HBr}$.

A. J. Balard said that when mercuric bromide is heated with **nitric acid**, it gives off the vapour of bromine. The action of ammonia is indicated in a later section. K. A. Hofmann and E. C. Marburg prepared a compound with hydrazine, $(\text{HgBr})_2\text{N}_2\text{H}_4$, analogous with the corresponding compound with mercuric chloride. They also prepared **mercuric hydrazine bromide**, $\text{HgBr}_2 \cdot \text{N}_2\text{H}_4$, also analogous with the chlorine compound. A. Ferratini prepared white prismatic crystals of **hydrazine tribromomercuriate**, $2\text{N}_2\text{H}_4 \cdot \text{HBr} \cdot \text{HgBr}_2 \cdot \text{H}_2\text{O}$, by mixing soln. of hydrazine hydrobromide and mercuric bromide in mol. proportions, and evaporating in vacuo. The crystals melt at about 73° , and decompose over 150° ; they are sparingly soluble in water, and acetic ether; soluble in alcohol and acetone; and insoluble in ether. M. Adams was not able to make a compound with hydroxylamine analogous with $\text{HgCl}_2 \cdot 2\text{NH}_2\text{OH}$; but he made white quadratic plates of **hydroxylamine tribromomercuriate**, $2\text{NH}_2\text{OH} \cdot \text{HBr} \cdot \text{HgBr}_2$, by mixing soln. of the component salts in methyl alcohol. The aq. and alcoholic soln. slowly decompose, forming mercurous bromide; the decomposition is rapid in alkaline soln. C. Löwig found that mercuric bromide and **phosphorus** give phosphorous bromide; and likewise

when heated with **antimony** or **arsenic**, mercuric bromide gives up its bromine to the metal. P. Lemoult observed that **phosphine** is copiously absorbed by soln. of mercuric bromide; and H. Rose said that a yellow precipitate is formed as in the case of mercuric chloride; the precipitate becomes black when boiled for a long time with water. H. Arctowsky noted that **calcium carbonate** (marble) gives similar results with soln. of mercuric bromide as with the chloride, and an oxybromide is formed. M. G. Kutscheroff obtained aldehyde by heating mercuric bromide with **acetylene** and water in a sealed tube. T. Harth noted that with two mols of **potassium cyanide** per mol of mercuric bromide, mercuric cyanide and potassium bromide are quantitatively formed, but with two mols of potassium bromide to one of mercuric cyanide no change was observed. H. Grossmann observed that with **potassium thiocyanate** mercuric bromide behaves in an analogous manner to the chloride. C. Löwig noted that a soln. of mercuric bromide is reduced to mercurous bromide when treated with **mercury**, **copper**, or a soln. of **cuprous bromide** in hydrobromic acid. **Potassium hydroxide** or **sodium hydroxide** was found by W. Sievers to colour mercuric bromide orange-yellow, forming mercuric oxide; while with a soln. of mercuric bromide, a brownish-black precipitate of a basic salt is formed if the alkali-lye be not in excess, but if it be in excess, mercuric oxide is formed. W. Herz has investigated the equilibrium conditions in this reaction.

As previously indicated, E. Beckmann,¹² W. C. Luczizky, and J. S. van Nest have shown that mercuric chloride and bromide probably form a continuous series of mixed crystals; but since the crystals obtained from a soln. of two salts in alcohol have the crystal-form of neither the chloride nor the bromide—the axial ratios being $a:b:c=0.6350:1:1.0308$, sp. gr. 5.918, and m.p. 213° —J. S. van Nest suggested that possibly a double salt, **trimercuric tetrabromodichloride**, $\text{HgCl}_2 \cdot 2\text{HgBr}_2$, can exist. M. Berthelot gave -6.4 Cals. for the heat of soln. of $\text{HgCl}_2 + \text{HgBr}_2$, and he added that the heat of combination is virtually nil.

H. Edhem-Bey spontaneously evaporated a soln. of mercuric chloroamide, NH_2HgCl , in a very dil. alcoholic soln. of bromine, and obtained plate-like crystals of **mercuric ammonium dibromochloride**, $\text{NH}_4\text{Cl} \cdot \text{HgBr}_2$. J. M. Thomson and W. P. Bloxam examined a sat. soln. of mercuric bromide and ammonium chloride with respect to crystallization when seeded with mercuric bromide or ammonium bromide—the former was active, the latter inactive. They assumed that the soln. contained **trihydrated ammonium mercuric dibromotrichloride**, $\text{HgBr}_2 \cdot 3\text{NH}_4\text{Cl} \cdot 3\text{H}_2\text{O}$. P. C. Ray obtained **ammonium dimercuric bromotetrachloride**, $\text{NH}_4\text{Br} \cdot 2\text{HgCl}_2$, by concentrating soln. of dimercuriammonium bromide, NH_2HgBr , in hydrochloric acid. V. Borelli prepared **mercuric perchloratobromide**, $\text{Br} \cdot \text{Hg} \cdot \text{ClO}_4$ —vide the corresponding iodide—in bundles or in mammillary masses of short white prisms. A soln. of mercuric bromide in one of the perchlorate depresses the f.p., and raises the b.p. It is inferred that mercuric bromide enters these soln. in the form of HgBr^+ -ions, and to a slight extent as $\text{Hg}_2\text{Br}_2^{++}$ -ions. The presence of complex ions is shown by the variations in the conc. of the mercuric bromide at the electrodes during electrolysis.

§ 20. Mercuric Oxybromides—Basic Mercuric Bromides

The remarks made about the mercuric oxychlorides apply also to the oxybromides. Many compounds have been reported, but many are probably not chemical individuals. Representing the ratio $\text{HgBr}:\text{HgO}$ in that order, the compounds 1:1, 1:2, 1:3, 1:3½, and 1:4 have been reported; and, of these, T. Fischer and H. von Wartenberg¹ believe that only the first two do not exist. In A. J. Balard's method of preparing hypobromous acid by the action of aq. bromine on mercuric oxide, it is often stated that the 1:1 oxybromide—**dimercuric oxybromide**, $\text{HgBr}_2\cdot\text{HgO}$, or Hg_2OBr_2 —is formed, but T. Fischer and H. von Wartenberg say that this is only an assumption, and that the product is really an oxybromate, $\text{HgO}\cdot\text{Hg}(\text{BrO}_3)_2$. G. André, however, claimed to have obtained grey crystals of this compound by heating a mixture of the two constituents in the required proportions in a sealed tube to 300°; and he says the heat of the reaction ($\text{HgBr}_2, \text{HgO}$) is 3.32 Cals. K. Thümmel also reported the formation of red quadratic plates of the 1:2 oxybromide—**trimercuric dioxybromide**, $\text{HgBr}_2\cdot 2\text{HgO}$, or $\text{Hg}_3\text{O}_2\text{Br}_2$ —by treating undried yellow mercuric oxide with a lukewarm soln. of mercuric bromide; and also by boiling a 1:50 soln. of mercuric bromide, 50 parts, with one part of sodium carbonate, and then digesting the product 12 hrs. at 35° to 40°. G. André made it by a process analogous to that used for $\text{HgBr}_2\cdot\text{HgO}$, and he says that the heat of formation ($\text{HgBr}_2, 2\text{HgO}$) is 4.4 Cals.

A citron-yellow crystalline powder of **tetramercuric trioxybromide**, $\text{HgBr}_2\cdot 3\text{HgO}$, or $\text{Hg}_4\text{O}_3\text{Br}_2$, was prepared by C. Löwig, and by T. Fischer and H. von Wartenberg, by adding insufficient potassium hydroxide to mercuric bromide to precipitate all the mercury, and subsequently boiling the mixture; G. André made it by melting together eq. quantities of the component salts; and K. Thümmel, by treating freshly precipitated mercuric oxide with a lukewarm sat. soln. of mercuric bromide; C. Löwig obtained it in a similar manner. C. F. Rammelsberg made a dark brown form of the same salt by precipitation from an aq. soln. of mercuric bromide by the addition of sodium carbonate. T. Fischer and H. von Wartenberg made it by adding to a cold alcoholic soln. of mercuric bromide insufficient alcoholic potash for complete precipitation, and washing the precipitate with alcohol. When heated, K. Thümmel found $\text{HgBr}_2\cdot 3\text{HgO}$ first formed $\text{HgBr}_2\cdot 4\text{HgO}$, then HgBr_2 and HgO ; and C. Löwig found that at a gentle heat it is resolved into oxygen, a sublimate of mercuric and mercurous bromides, and a residue of mercuric oxide. C. Löwig said that this oxybromide is insoluble in cold water, sparingly soluble in hot water, and soluble in alcohol, but the fact that C. F. Rammelsberg found it to be insoluble in alcohol, makes it probable that C. Löwig's product contained some free mercuric bromide. K. Thümmel says cold alcohol decomposes it, forming mercurous bromide. The reports of the properties of this compound are therefore not concordant.

C. F. Rammelsberg also found the compound is not changed by boiling potash-lye, while C. Löwig says it is wholly converted into mercuric oxide. Ammonia was found by T. Fischer and H. von Wartenberg to convert it into dimercuriammonium oxybromide. C. F. Rammelsberg says that nitric acid dissolves out the mercuric oxide and leaves mercuric bromide as a residue.

T. Fischer and H. von Wartenberg reported the formation of the 1 : 3½ compound—**enneameric heptoxybromide**, $2\text{HgBr}_2 \cdot 7\text{HgO}$. Brown rhombic plates (yellow in transmitted light) of sp. gr. 9.13, are obtained by heating a mixture of 4.3 grms. of mercuric oxide, 14.4 grms. of mercuric bromide, in 30 c.c. of water for 5 hrs. in a sealed tube at 150°, and afterwards washing the product with hot alcohol; and also by heating a mixture of the two components in a sealed tube at 250°. T. Fischer and H. von Wartenberg also obtained another form of this salt in black rhombic crystals (reddish-brown in transmitted light), and of sp. gr. 8.25, by treating a sat. soln. of mercuric bromide at 60° with a sat. soln. of potassium hydrogen carbonate, and after standing the mixture for two hours, filtering and washing. This compound is decomposed by acids and alkalies, and by potassium bromide, forming mercuric bromide. Ammonia forms dimercuriammonium oxybromide. G. André gives the heat of formation ($\text{HgBr}_2, 3\text{HgO}$) as 6.32 Cals.

K. Thümmel obtained the 1 : 4 compound—**pentameric tetroxybromide**, $\text{HgBr}_2 \cdot 4\text{HgO}$ —by heating the 1 : 3 compound either alone or in the presence of water. K. Thümmel, G. André, and T. Fischer and H. von Wartenberg made it by the action of sodium carbonate on a soln. of mercuric bromide; and T. Fischer and H. von Wartenberg made it by the action of potassium hydrogen carbonate on mercuric bromide; by heating a mixture of equimolar proportions of the component salts in the presence of water in a sealed tube at 160°, and subsequently washing out the mercuric bromide with water; by heating in a sealed tube at 200°–300°, a mixture of 8.6 grms. of mercuric oxide and 7.2 grms. of mercuric bromide; by leaving a soln. of mercuric bromide for some weeks in contact with marble or magnesite; and by the action of ozonized air on a slurry of mercurous bromide and water—any mercuric bromide which is formed is removed by alcohol. G. André made it by heating 50 grms. each of red mercuric oxide and mercuric bromide in a litre of water for 12 hrs. to near the b.p. The dark reddish-brown crystalline powder has a sp. gr. 8.73. It is decomposed by heat at 230° into mercuric oxide, and a sublimate of the bromide. Dry ammonia has no action, while aq. ammonia, a soln. of potassium bromide, acids or alkalies act like they do on the 1 : 3½ compound. According to G. André, the heat of formation ($\text{HgBr}_2 \cdot 4\text{HgO}$) is 7.8 Cals. The heats of formation of the mercuric oxybromides were found by G. André to be somewhat greater than those of the corresponding oxychlorides.

§ 21. Compounds of Mercury, Bromine, and Ammonia

Mercuric bromide was found by G. Gore¹ to be moderately soluble in liquid ammonia. According to H. Rose, cold mercuric bromide does not absorb ammonia gas; but when fused at a gentle heat, and cooled in an atm. of the gas, it absorbs 3.41 per cent. approximately eq. to $2\text{HgBr}_2 \cdot \text{NH}_3$. The analyses of the product by H. Rose and E. Mitscherlich are not concordant—presumably on account of the volatilization of some mercuric salt when heated. When the product is treated with water, ammonium bromide passes into soln. and a yellow powder

remains which C. F. Rammelsberg found to give off ammonia gas when treated with potassium sulphide, but not with the hydroxide. According to W. Peters, a mol of mercuric bromide takes up two mols of ammonia when treated in H. Ley and G. Wiegner's apparatus. When aq. soln. of mercuric bromide are treated with aqua ammonia, a white precipitate of the bromamide is obtained: $\text{HgBr}_2 + 2\text{NH}_3 = \text{NH}_4\text{Br} + \text{Hg}(\text{NH}_2)\text{Br}$. The product is the bromine analogue of infusible white precipitate, NH_2HgCl . J. G. F. Druce said that aq. ammonia reacts with mercurous bromide, forming a mixture of mercury and mercuric bromamide.

Sat. soln. of mercuric bromide in methyl or ethyl acetate give a white precipitate of **mercuric diamminobromide**, $\text{HgBr}_2 \cdot 2\text{NH}_3$. A. Naumann and F. Becker used a half-sat. soln. of mercuric chloride in benzonitrile. J. Schröder also examined the action of ammonia on soln. of mercuric bromide in pyridine. R. Widman and L. Pesci also made the diammino-compound by incomplete precipitation from mercuric bromide; and by adding a few drops of ammonia to a soln. of 0.08 gm. of ammonium bromide per c.c. of water sat. with mercuric bromide.

H. Gaudechon made it by pouring a soln. of 50 grms. of mercuric bromide, and 80 grms. of ammonium bromide and 400 c.c. of water, into 100 c.c. of aqua ammonia such that the mol. ratio in the two soln. $\text{NH}_3 : \text{HgBr}_2$ is greater than 2 : 1. The precipitate was washed by decantation with cold water until it began to show a faint yellow tinge; and it was then allowed to stand in contact with a very dil. soln. of ammonium chloride for some hours until the white colour of the precipitate is restored. The precipitate was then drained, dried on porous tiles, and finally over barium oxide at ordinary temp.

L. Pesci made it by treating dimercuriammonium bromide, $\text{NH}_2\text{Hg}_2\text{Br}$, or the double salt of this compound with ammonium bromide, with a boiling soln. of ammonium bromide; and by the action of alcoholic ammonia on mercuric bromide.

H. Gaudechon found that if a soln. of mercuric bromide at 80° be poured into an excess of ammonia either $\text{HgBr}_2 \cdot 2\text{NH}_3$ or $\text{NH}_2\text{Hg}_2\text{Br}$ is formed—all depends on the concentration. He studied mixed soln. of mercuric and ammonium bromides and water in equilibrium with solid phases, and on plotting the conc. of the elements bromine (or nitrogen) and mercury in soln. obtained curves resembling those indicated in Fig. 23. The breaks in the curves corresponded with the solid phases, $\text{HgBr}_2 \cdot 4\text{NH}_2\text{Br}$; $\text{Hg}(\text{NH}_2)\text{Br}$; and $\text{HgBr}_2 \cdot 2\text{NH}_3$, as shown in the diagram.

FIG. 23.—Equilibrium of Mercury, Bromine, and Aqueous Ammonia.

According to E. C. Franklin, and F. F. Fitzgerald, a soln. of mercuric bromide in liquid ammonia undergoes aminolysis: $2\text{HgBr}_2 + 4\text{NH}_3 \rightleftharpoons \text{NH}_2\text{Hg}_2\text{Br} + 3\text{NH}_4\text{Br}$; and R. Widman found that with an excess of aqua ammonia on mercuric bromide, the compounds $\text{Hg}(\text{NH}_2)\text{Br}$ and $\text{NH}_2\text{Hg}_2\text{Br}$ are formed: $\text{HgBr}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{Hg}(\text{NH}_2)\text{Br} + \text{NH}_4\text{Br}$; and $2\text{Hg}(\text{NH}_2)\text{Br} \rightleftharpoons \text{NH}_2\text{Hg}_2\text{Br} + \text{NH}_4\text{Br}$; followed by $\text{NH}_2\text{Hg}_2\text{Br} + 2\text{H}_2\text{O} \rightleftharpoons 2\text{HgO} + \text{NH}_4\text{Br}$. R. Widman also determined the equilibrium conc. of the first two equations, but the extreme slowness of the reaction last symbolized, and the low conc. of the ammonium bromide in soln., prevented the equilibrium conditions being established. It therefore follows that in the presence of an excess of aqua ammonia, mercuric chloride and bromide behave in a similar manner, excepting that with mercuric chloride there is a hydrolysis, forming $\text{HgOH}-\text{NH}-\text{HgCl}$, whereas with mercuric bromide the hydrolysis occurs in the final stage involved in the formation of mercuric oxide.

Both R. Widman and H. Gaudechon agree that in contact with water alone, mercuric diamminobromide decomposes, forming $\text{Hg}(\text{NH}_2)\text{Br}$ and $\text{HgBr}_2 \cdot 4\text{NH}_2\text{Br}$, in accord with the symbols: $\text{HgBr}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{Hg}(\text{NH}_2)\text{Br} + \text{NH}_4\text{Br}$; followed by the aminolysis and diammonation of the basic salt, mercuric bromoamide: $9\text{Hg}(\text{NH}_2)\text{Br} \rightleftharpoons \text{HgBr}_2 \cdot 4\text{NH}_2\text{Br} + 3\text{NH}_4\text{Br} + 2\text{NH}_3$. The further hydrolysis has not been determined, but R. Widman has shown that in the absence of free ammonia,

ammonium bromide soln. acts on mercuric oxide in agreement with the symbols : $9\text{HgO} + 6\text{NH}_4\text{Br} \rightleftharpoons 2\text{NH}_3 + 9\text{H}_2\text{O} + \text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$. In the presence of an excess of mercuric bromide, R. Widman found both $\text{Hg}(\text{NH}_2)\text{Br}$ and $\text{NH}(\text{HgBr})_2$ are formed, and he has established the reactions : $\text{HgBr}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{Hg}(\text{NH}_2)\text{Br} + \text{NH}_4\text{Br}$; followed by $2\text{Hg}(\text{NH}_2)\text{Br} \rightleftharpoons \text{NH}(\text{HgBr})_2 + \text{NH}_3$; and by $2\text{NH}(\text{HgBr})_2 + 3\text{H}_2\text{O} \rightleftharpoons 3\text{HgO} + 2\text{NH}_4\text{Br} + \text{HgBr}_2$, and he has further shown that the aminobasic salt $\text{NH}(\text{HgBr})_2$ is successively aminolyzed into $\text{Hg}_9\text{N}_4\text{Br}_6$, and then into NHg_2Br , in accord with the equations : $9\text{NH}(\text{HgBr})_2 + 5\text{NH}_3 = 2\text{Hg}_9\text{N}_4\text{Br}_6 + 6\text{NH}_4\text{Br}$; followed by $2\text{Hg}_9\text{N}_4\text{Br}_6 + 4\text{NH}_3 \rightleftharpoons 9\text{NHg}_2\text{Br} + 3\text{NH}_4\text{Br}$.

Mercuric diamminobromide is the bromine analogue of fusible white precipitate. L. Pesci, and H. Gaudechon supposed it to be $\text{NHg}_2\text{Br} \cdot 3\text{NH}_4\text{Br}$, and the latter, on this assumption, gave its heat of formation from the solid compound salts as 9.4 Cals. M. Hamers, and A. Naumann say that mercuric diamminobromide is a white powder without any smell ; it melts when heated to 180° , giving off ammonia, and forming a white sublimate. At a higher temp. it forms two volatile substances, one of which forms a pulverulent sublimate and the other condenses as a liquid which solidifies to a crystalline mass. E. Clerici has measured the viscosity constants of the molten liquid. When suspended in water, and treated with hydrogen sulphide, it forms mercuric sulphide and ammonium bromide. It is decomposed by water changing to a yellow colour, and when boiled with water, it breaks down and forms a soln. containing but little mercury, and much ammonia—the reactions involved will appear from what has been said above ; similar remarks apply to the action of aqua ammonia, and soln. of mercuric bromide and of ammonium bromide. L. Pesci says that soln. of ammonium chloride, bromide, or iodide slowly dissolve the salt with the evolution of ammonia. Alkali-lye decomposes it, forming ammonia and dimercuriammonium bromide, NHg_2Br . It is readily soluble in hydrochloric acid. The soln. in hot dil. sulphuric acid deposits crystals of mercuric bromide on cooling, and it is soluble in acetic acid, but not in alcohol. According to W. Peters, the salt loses ammonia in vacuo. F. Anderlini prepared dark blue crystals of **cupric mercuric tetramminotetrabromide**, $\text{CuHgBr}_4 \cdot 4\text{NH}_3$, by mixing a boiling soln. of ammoniacal cupric bromide, and a soln. of mercuric and potassium bromides ; and bright blue scales or needles of $\text{CuHg}_2\text{Br}_6 \cdot 4\text{NH}_3$, by treating a soln. of the preceding compound in a warm soln. of ammonium bromide with mercuric bromide dissolved in potassium bromide in the presence of free ammonia—not in excess.

The bromine analogue of infusible white precipitate was prepared by C. Löwig² in 1828, and studied by E. Mitscherlich in 1840. Similar remarks apply to the constitution of both mercuric chloroamide, and bromoamide. According to C. F. Rammelsberg, L. Pesci, H. Gaudechon, and other supporters of the diammonium hypothesis, this compound is assumed to be a double compound of ammonium and dimercuriammonium bromides—namely, $\text{NH}_4\text{Br} \cdot \text{NHg}_2\text{Br}$; while, according to R. J. Kane's hypothesis, it is **mercuric bromamide**, $\text{NH}_2\text{—Hg—Br}$, or possibly, according to E. C. Franklin, $\text{HgBr}_2 \cdot \text{Hg}(\text{NH}_2)_2$. C. Löwig, E. Mitscherlich, and L. Pesci made this compound by adding aqua ammonia to a soln. of mercuric bromide. The same compound was found by R. Widman to be a product of the action of mercuric bromide on mercuric diamminobromide.

Mercuric bromoamide is a white powder which is less stable the higher the temp. ; according to C. Löwig, it decomposes when heated into nitrogen, ammonia, steam, and a sublimate of mercurous bromide, or, as E. Mitscherlich said, of $\text{HgBr}_2 \cdot \text{NH}_3$; the residue is $\text{HgBr}_2 \cdot 2\text{NHg}_2\text{Br}$. E. Mitscherlich also says that this compound is insoluble in water and alcohol. L. Pesci noted an indefinitely large proportion of ammonium bromide could be extracted by washing with water ; and that boiling water produces a yellow product which approximates closer and closer to NHg_2Br . H. Gaudechon says that water decomposes it, forming $\text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$; the reaction at 15° is represented by $9\text{Hg}(\text{NH}_2)\text{Br} = \text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br} + 2\text{NH}_3 + 3\text{NH}_4\text{Br}$; and at 100° , $10\text{Hg}(\text{NH}_2)\text{Br} = \text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br} + 2\text{NH}_4\text{Br} + 4\text{NH}_3 + \text{HgBr}_2$. E. Mitscherlich found it to be slightly soluble in aqua ammonia ; and

H. Gaudechon noted that after standing at 8° to 10° in contact with ammonium bromide the solid phase is $\text{HgBr}_2 \cdot 2\text{NH}_3$. H. Gaudechon and R. Widman have studied the equilibrium conditions. H. Saha and K. N. Choudhuri obtained **dihydrated mercuric oxybromoamide**, $\text{HgO} \cdot \text{Hg}(\text{NH}_2)\text{Br} \cdot 2\text{H}_2\text{O}$, by shaking aqua ammonia of sp. gr. 0.895 with mercurous bromide, and evaporating the ammoniacal filtrate in vacuo over sulphuric acid; the resulting white powder was washed with water and dried over calcium chloride. When heated, ammonia is evolved and a black mass remains, and at a higher temp. a sublimate of mercurous bromide and mercury is formed. Boiling potash-lye colours it yellow.

Mercuric hydroxybromoamide, $\text{HgOH} \cdot \text{NH} \cdot \text{HgBr}$.—This compound can be regarded as the bromide of Millon's base, it can also be regarded as *oxydimercuri-ammonium bromide*, $\text{OHg}_2\text{NH}_2\text{Br}$, or as *hydrated dimercuri-ammonium bromide*. Graphically:

It is formed, according to P. C. Ray, when the salt $\text{NH}_4\text{Br} \cdot 4\text{HBr}$ is treated with an excess of potassium hydroxide. K. A. Hofmann and E. C. Marburg made it by digesting Millon's base in darkness for 24 hrs. with a 3 per cent. soln. of hydrobromic acid, washing the product with the same acid, then with alcohol and ether, and drying 24 hrs. in vacuo over sulphuric acid. Attempts to dehydrate the product have been nugatory; it decomposes at 200°. K. A. Hofmann and E. C. Marburg also prepared what they regarded as *dihydrated dimercuri-ammonium bromide*, $\text{NHg}_2\text{Br} \cdot 2\text{H}_2\text{O}$, but what E. C. Franklin regarded as **hydrated mercuric hydroxybromoamide**, $\text{HgOH} \cdot \text{NH} \cdot \text{HgBr} \cdot \text{H}_2\text{O}$. The alternative formula, $(\text{HgOH})_2\text{NH}_2\text{Br}$, has also been suggested. This compound is formed as a yellow powder by treating an aq. soln. of mercuric bromide with dil. aqua ammonia, and washing the product with dil. ammonia, then with alcohol and ether, and finally drying in vacuo.

L. Pesci prepared what he regarded as a double salt, $4\text{NHg}_2\text{Br} \cdot 5\text{NH}_4\text{Br}$, but which E. C. Franklin regarded as **mercuric diammino-enneabromoamide**, $7\text{Hg}(\text{NH}_2)\text{Br} \cdot \text{HgBr}_2 \cdot 2\text{NH}_3$, by the action of ammonium carbonate on an aq. soln. of mercuric bromide; by passing carbon dioxide through a strongly ammoniacal soln. of mercuric bromide; or by allowing the soln. to stand exposed to the air. The product is washed with a dil. soln. of ammonium carbonate, and dried over sulphuric acid. It forms minute needle-like crystals, which, when heated, decompose without melting, forming ammonia, etc. The compound is decomposed by water, forming ammonium bromide and mercuric bromoamide. Hot alkali-lye transforms it into dimercuri-ammonium bromide, NHg_2Br , with the evolution of ammonia. It is easily soluble in hydrochloric acid; insoluble in conc. nitric acid; and it is soluble in a warm 10 per cent. soln. of sulphuric acid—and on cooling, the last-named soln. deposits crystals of mercuric bromide. It dissolves slowly in soln. of ammonium chloride, bromide, or iodide with the evolution of ammonia. The constitution and therefore also the name of this product is not clear; nor is it known if a true compound or mixed crystals of two or more compounds are in question.

R. Widman prepared **mercuric dibromoamide**, $\text{NH}(\text{HgBr})_2$, by treating mercuric bromoamide, $\text{Hg}(\text{NH}_2)\text{Br}$, with a soln. of mercuric bromide: $3\text{Hg}(\text{NH}_2)\text{Br} + \text{HgBr}_2 \rightleftharpoons 2\text{NH}(\text{HgBr})_2 + \text{NH}_4\text{Br}$ —*vide supra*—and also by shaking mercuric oxide with a soln. of mercuric and ammonium bromides. The white powder is rapidly blackened by exposure to diffuse daylight; it is decomposed by water; a dil. ammoniacal soln. of ammonium bromide converts it back into mercuric bromoamide.

Mercuric tetrabromoamide, $(\text{HgBr})_2\text{N} \cdot \text{Hg} \cdot \text{N}(\text{HgBr})_2$, is also regarded by E. C. Franklin as possibly having the composition $2\text{HgBr}_2 \cdot \text{Hg}_3\text{N}_2$; and by H. Gaudechon as having the composition $2\text{NHg}_2\text{Br} \cdot \text{HgBr}_2$, which he calls *dimercuri-ammonium dibromomercuriate*; and he gives the heat of formation from the solid component salts as 10.9 Cals. H. Gaudechon made it by treating a more or less conc. soln. of mercuric bromide at 80° with sufficient ammonia for the mol. ratio $\text{HgBr}_2 : \text{NH}_3$ not to exceed 1:18. P. C. Ray made it by gradually adding potash-lye—not in excess—to a boiling soln. of ammonium pentabromomercuriate,

$\text{NH}_4\text{Br} \cdot 2\text{HgBr}_2$. When the yellow powder is digested with water, it gives up so little mercury, bromine, and nitrogen to the solvent that H. Gaudechon could not decide whether the soluble matter was due to decomposition or soln. It is decomposed by hot water into dimercuriammonium bromide, NHg_2Br , and *dimercuriammonium hexabromomercuriate*, $\text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$.

H. Gaudechon explains the formation of the compounds $\text{HgCl}_2 \cdot 2\text{NHg}_2\text{Cl}$, and of $\text{HgBr}_2 \cdot 2\text{NHg}_2\text{Br}$, on the assumption that the halogen salts of dimercuriammonium when given the choice of water, or ammonium or mercuric halide, unite by preference with the mercuric halide to form what he calls in the case of $\text{HgCl}_2 \cdot 2\text{NHg}_2\text{Cl}$, *chloromercurate de dimercuriammonium*, and in the case of $\text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$, *bromomercurate de dimercuriammonium*. E. C. Franklin regards these compounds as aminobasic salts or mixtures formed in the presence of insufficient ammonia to give basic compounds richer in nitrogen; and he shows that the structural formulation applied to ordinary basic salts is also applicable:

H. Gaudechon made the compound $\text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$, or $(\text{HgBr})_2\text{N} \cdot \text{Hg} \cdot \text{N}$: $[\text{Hg} \cdot \text{N}(\text{HgBr})_2]_2$, by pouring a litre of an aq. soln. of mercuric bromide sat. at 15° into a litre of aqua ammonia so that the mol. ratio $\text{HgBr}_2 : \text{NH}_3$ is rather more than 1 : 2. Next day the liquid was decanted from the orange-yellow precipitate, and the precipitate washed free from bromine and ammonia by cold or lukewarm water, and dried on porous tiles at 15° , and then in darkness at 100° . H. Gaudechon also obtained this same product by using an ammoniacal soln. of ammonium bromide with the soln. of mercuric bromide; and by washing $\text{Hg}(\text{NH}_2)\text{Br}$ or $\text{HgBr}_2 \cdot 2\text{NH}_3$ with hot or cold water until the washings are free from bromine or ammonia. R. Widman studied the conditions of equilibrium of this salt with soln. of ammonia and ammonium bromide—*vide supra*—with aqua ammonia it forms mercuric bromoamide, $2\text{N}_4\text{Hg}_6\text{Br}_6 + 4\text{NH}_3 = 9\text{NHg}_2\text{Br} + 3\text{NH}_4\text{Br}$. According to H. Gaudechon, the heat of formation of $\text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$, from the solid component salts is 15.2 Cals.

Dimercuriammonium bromide, or *tetramercuriammonium bromide*, NHg_2Br .—This product may be regarded as a basic mixture, $\text{HgBr}_2 \cdot \text{Hg}_3\text{N}_2$. L. Pesci made it by treating dimercuriammonium enneabromomercuriate, $5\text{NH}_4\text{Br} \cdot 4\text{NHg}_2\text{Br}$, or $\text{HgBr}_2 \cdot 7\text{Hg}(\text{NH}_2)\text{Br} \cdot 2\text{NH}_3$, with warm alkali-lye, or by treating Millon's base with dil. hydrobromic acid, and, in either case, drying the product in vacuo over sulphuric acid. H. Gaudechon made it by treating two mols of dimercuriammonium hexabromomercuriate, $\text{HgBr}_2 \cdot 4\text{NHg}_2\text{Br}$, with four mols of ammonia in a hot conc. soln., and drying the product at 100° , or else at 15° over barium oxide. H. Gaudechon also made it by treating dimercuriammonium oxide, $(\text{NHg}_2)_2\text{O} \cdot 2\text{H}_2\text{O}$, with hydrobromic acid for 24 hrs. in darkness, drying the product on porous tiles, and finally at 15° over barium oxide, and then at 100° . E. C. Franklin made it by adding a soln. of potassium amide to an excess of a soln. of mercuric bromide in liquid ammonia, and thoroughly shaking the mixture. F. F. Fitzgerald made it by thoroughly mixing an aq. soln. of potassium amide with an excess of a similar soln. of mercuric bromide, and after standing 24 hrs., washing the precipitate. R. Widman said that this compound is precipitated from ammoniacal soln. of mercuric bromide, when the conc. of ammonium bromide is less than 0.0008 gm. per c.c. If a hot soln. of mercuric bromide is poured into a cold aq. soln. of ammonia, a white or yellow precipitate is formed, which, when washed with water, furnishes **monohydrated dimercuriammonium bromide**, $\text{NHg}_2\text{Br} \cdot \text{H}_2\text{O}$. If the soln. be mixed in the converse way, and the precipitate be washed, a deep yellow precipitate of dimercuriammonium hexabromomercuriate is formed. If the latter

be well washed with hot conc. ammonia, a canary-yellow dimercuriammonium bromide is formed. This does not combine with water to form the monohydrate, nor is the anhydrous salt formed by heating the monohydrate.

Dimercuriammonium bromide is a canary-yellow powder, which H. Gaudechon found to consist of very small crystals. According to this *savant*, the heat of formation of this compound from its elements is -17.6 Cals. L. Pesci said that when heated, it decomposes without melting, giving off ammonia; and H. Gaudechon said that it explodes if rapidly heated to redness, but if gradually heated to 400° , blue sparks appear in the mass and mercury and mercurous bromide are formed. This salt is insoluble in water, and it is not hydrated after standing 15 days in water or in an atm. sat. with water vapour; L. Pesci said that it is insoluble in conc. nitric or sulphuric acid, and F. F. Fitzgerald obtained only a small residue—probably mercurous bromide, when the salt is boiled for a long time with sulphuric acid; it is readily soluble in hydrochloric acid. E. C. Franklin found it to be soluble in aq. soln. of acid, and ammoniacal salts; and L. Pesci found it to dissolve slowly in soln. of ammonium chloride, bromide, or iodide with the evolution of ammonia. R. Widman, and H. Gaudechon have studied the conditions of equilibrium of this compound with water and ammoniacal salts—*vide supra*. E. C. Franklin found it to be converted into mercuric nitride, Hg_3N_2 , by potassium amide.

What P. C. Ray regarded as *hemihydrated dimercuriammonium bromide*, $2\text{NHg}_2\text{Br} \cdot \text{H}_2\text{O}$, and E. C. Franklin as **dimercuriammonium hydroxybromoamide**, $\text{NHg}_2\text{Br} \cdot \text{HgOH} \cdot \text{NH} \cdot \text{HgBr}$, was made as a deep red precipitate by P. C. Ray, and J. Sen, by treating $\text{NH}_4\text{Br} \cdot 2\text{HgBr}_2$ with an excess of dil. potassium hydroxide, and drying at 100° . This product is decomposed by heat into nitrogen, mercury, water, and mercurous bromide. The salt, $\text{NHg}_2\text{Br} \cdot \text{H}_2\text{O}$, is considered to be $\text{HgOH} \cdot \text{NH} \cdot \text{HgBr}$; and $\text{NHg}_2\text{Br} \cdot 2\text{H}_2\text{O}$, to be $\text{HgOH} \cdot \text{NH} \cdot \text{HgBr} \cdot \text{H}_2\text{O}$.

H. Gaudechon made **dimercuriammonium hemiamminobromide**, $2\text{NHg}_2\text{Br} \cdot \text{NH}_3$, by exposing dimercuriammonium bromide to the action of ammonia under press. When the contents of the tube have changed to a red colour, the tube is cooled so as to liquefy the ammonia. The tube is then opened, and the excess of liquid ammonia poured off. The product is then allowed to stand in a bath of methyl chloride at -21° until no more gas is developed. The red product can be kept at 4° – 5° without much change, but in 15 hrs. at 15° , it loses about one-third of its ammonia, and if kept over phosphorus pentoxide, it loses one-fourth of its ammonia, forming hydrated dimercuriammonium aminobromide, $4\text{NHg}_2\text{Br} \cdot \text{NH}_3 \cdot \text{H}_2\text{O}$, as a hygroscopic powder:

The compound *dimercuriammonium hydrobromide*, $\text{NHg}_2\text{Br} \cdot 4\text{HBr}$, is considered to be ammonium pentabromomercuriate, $2\text{HgBr}_2 \cdot \text{NH}_4\text{Br}$; the compound $\text{NHg}_2\text{Br} \cdot \text{HBr}$ is supposed to be $\text{NH}(\text{HgBr})_2$, the dibromide of Millon's base, or mercuric dibromoamide; the compound $\text{NHg}_2\text{Br} \cdot \text{NH}_4\text{Br}$ is better regarded as mercuric bromoamide, $\text{Hg}(\text{NH}_2)\text{Br}$; the compound $4\text{NHg}_2\text{Br} \cdot 5\text{NH}_4\text{Br}$ is also considered to be mercuric diammino-ennabromoamide, $7\text{Hg}(\text{NH}_2)\text{Br} \cdot \text{HgBr}_2 \cdot 2\text{NH}_3$; and the compound $\text{NHg}_2\text{Br} \cdot 3\text{NH}_4\text{Br}$ may be regarded as mercuric diamminobromide, $\text{HgBr}_2 \cdot 2\text{NH}_3$.

According to M. Adams,³ hydroxylamine does not unite with mercuric bromide to form stable salts of the type $\text{MBr}_2(\text{NH}_2\text{OH})_2$. An alcoholic soln. of normal hydroxylamine hydrobromide, cooled below zero, dissolves mercuric oxide, but the cold soln., on standing, furnishes white crystals of dihydroxylamine hydrobromide: $\text{HgO} + 4(\text{NH}_4\text{OH} \cdot \text{HBr}) = \text{HgBr}_2 + 2(\text{NH}_2\text{OH})_2\text{HBr} + \text{H}_2\text{O}$. If mol. proportions of the two salts, in methyl alcohol soln., cooled below zero, be treated with a methyl alcohol soln. of hydroxylamine, and ether added, microscopic quadratic plates of **mercuric tetrahydroxylamine dihydrobromide**, $\text{HgBr}_2(\text{NH}_2\text{OH})_2(\text{NH}_2\text{OH} \cdot \text{HBr})_2$, are formed. The crystals are soluble in methyl alcohol, forming a soln. which decomposes slowly; the aq. soln. decomposes rapidly. The salt is less stable than the corresponding chloride. The methods used for the preparation of mercuric dihydroxylamine chloride fail when employed in the attempt to make the corresponding bromide.

§ 22. Double and Complex Salts of Mercuric Bromide—The Bromomercuriates

According to R. Varet,¹ the double bromides are derivatives of the complex acids HHgBr_4 and $\text{H}_2\text{Hg}_2\text{Br}_6$. C. Löwig noted that hydrobromic acid of sp. gr. 1.18 when sat. at 40° with mercuric bromide, forms a syrupy liquid in which the two components are in the proportions $\text{HBr} \cdot \text{HgBr}_2$, that is, **hydrotribromomercuric acid**, HHgBr_3 ; and G. Neumann adds that this compound exists only at temp. exceeding 4°. R. Varet gives the heat of formation $\text{HBr} + \text{HgBr}_2 = 2.54$ Cals. and $2\text{HBr} + \text{HgBr}_2 = 2.30$ Cals. at 17°, and M. Berthelot gives HgBr_2 (one eq. in 40 litres) + 2HBr (one eq. in two litres) = 3.4 Cals. at 11°, and with 4HBr, under similar conditions, 5.4 Cals. with crystalline $\text{HgBr}_2 \cdot 4\text{HBr}$ in a soln. of similar concentrations, 3.0 Cals., and with 12HBr , 2.0 Cals. The properties of the product resemble those of the corresponding hydrotrichloromercuric acid. C. R. Crymble also noted the resemblance between the complexes HHgCl_3 and HHgBr_3 . If the soln. of hydrotribromomercuric acid be cooled or diluted with water, half the mercuric bromide is precipitated and the compound $2\text{HBr} \cdot \text{HgBr}_2$, that is, **dihydro-tetrabromomercuric acid**, H_2HgBr_4 , remains in soln., and G. Neumann added that this product is formed in soln. at 11°. C. Löwig noted that mercuric bromide is readily soluble in soln. of ammonium bromide, and that the addition of alkali carbonates precipitates mercuric bromoamide, $\text{Hg}(\text{NH}_2)\text{Br}$.

P. C. Ray prepared crystals of **ammonium pentabromomercuriate**, $2\text{HgBr}_2 \cdot \text{NH}_4\text{Br}$, or $\text{NH}_4\text{Hg}_2\text{Br}_5$, by the action of hydrobromic acid on dimercuri-ammonium nitrite. The soln. is then evaporated; the same salt is made by evaporating a soln. of the component salts in the presence of hydrobromic acid. The white prismatic and tabular crystals probably belong to the triclinic system; they are decomposed by water into their components; alkali hydroxides form $\text{NHg}_2\text{Br} \cdot \frac{1}{2}\text{H}_2\text{O}$, i.e. $\text{NHg}_2\text{Br} \cdot \text{HgOH} \cdot \text{NH} \cdot \text{HgBr}$; and also $2\text{NHg}_2\text{Br} \cdot \text{HgBr}_2$, i.e. $(\text{HgBr})_2\text{N} \cdot \text{Hg} \cdot \text{N}(\text{HgBr})_2$. E. Clerici has measured the viscosity constants. R. Varet gives the heat of formation 2.22 Cals. by mixing soln. of the component salts; R. Varet also gave 2.63 Cals. for the hypothetical $\text{HgBr}_2 \cdot \text{NH}_4\text{Br}$. An alternative formulation for $2\text{HgBr}_2 \cdot \text{NH}_4\text{Br}$ is $\text{NHg}_2\text{Br} \cdot 4\text{HBr}$.

R. Varet² deduced the formation of **lithium tribromomercuriate**, $\text{HgBr}_2 \cdot \text{LiBr}$, with a heat of formation of 1.35 Cals., and of **lithium tetrabromomercuriate**, $\text{HgBr}_2 \cdot 2\text{LiBr}$, with a heat of formation of 2.50 Cals., by mixing aq. soln. of the

component salts. F. Calzolari and U. Tagliavini prepared **lithium mercuric bromodichloride**, or *lithium bromodichloromercuriate*, $\text{HgCl}_2 \cdot \text{LiBr}$, but could not get it in the crystalline form; although the complex with hexamethylenetetramine readily crystallized. P. A. von Bonsdorff prepared deliquescent needles and rhombic prisms of sodium bromomercuriate; and T. Harth also prepared this salt. E. Clerici determined the viscosity constants. R. Varet gave the heat of formation of **sodium tribromomercuriate**, $\text{HgBr}_2 \cdot \text{NaBr}$, as 1.28 Cals. at 17° , and of **sodium tetrabromomercuriate**, $\text{HgBr}_2 \cdot 2\text{NaBr}$, as 2.30 Cals. A. Vicario preferred the last-named salt to mercuric bromide for hypodermic injections; the soln. is quite neutral and does not coagulate albumen. A. Vicario also prepared **sodium dichlorodibromomercuriate**, $\text{HgBr}_2 \cdot 2\text{NaCl}$, from soln. of the component salts.

According to C. Löwig, a conc. aq. soln. of two mols of potassium bromide dissolves more than three mols of mercuric bromide, forming a stiff opaque mass which when cooled or diluted with water, deposits mercuric bromide until two mols remain in soln. W. Herz and W. Paul measured the solubility of mercuric bromide in soln. of potassium bromide at 25° . Expressing the results in milligram-mols per 10 c.c.:

KBr	.	.	0	2.19	7.70	23.80	34.70
HgBr ₂	.	.	0.17	0.98	4.72	13.60	19.30

When the soln. of equimolar parts of the two salts is evaporated, P. A. von Bonsdorff obtained prismatic crystals of what is thought to be **potassium tetrabromomercuriate**, $\text{HgBr}_2 \cdot 2\text{KBr}$, or K_2HgBr_4 . These crystals are stable in air. According to J. Thomsen, the heat of formation ($\text{Hg}, \text{Br}_2, 2\text{KBr}, \text{aq.}$) = 52.19 Cals., ($\text{HgBr}_2, 2\text{KBr}$) = 1.23 Cals.; ($\text{HgBr}_2, 2\text{KBr}, \text{aq.}$) = 1.64 Cals.; and for solid K_2HgBr_4 , 242.4 Cals. The heat of soln. of a mol of K_2HgBr_4 in 600 mols of water is -9.75 Cals. M. Berthelot gives the heat of formation in soln. at 8° , as ($\text{HgBr}_2 \cdot 2\text{KBr}$), 5.0 Cals., and for $\text{HgBr}_{2\text{aq.}} + 4\text{KBr}_{\text{aq.}}$ = 8.2 Cals., and of $\text{HgBr}_{2\text{aq.}} + 8\text{KBr}$ = 9.6 Cals., so that higher double salts than the 1 : 2 compound are supposed to be formed. R. Varet gives for the heat of formation $\text{HgBr}_2 \cdot 2\text{KBr}$, 2.36 Cals. S. Bugarszky represents the equilibrium conditions between a soln. of potassium bromide and yellow mercuric oxide by $4\text{KBr} + \text{HgO} + \text{H}_2\text{O} \rightleftharpoons 2\text{KOH} + \text{K}_2\text{HgBr}_4$. R. G. van Name and W. G. Brown studied the equilibrium conditions in soln. of mercuric and potassium bromides, and obtained evidence of the formation of the double salt, $2\text{KBr} \cdot \text{HgBr}_2$. Yellow octahedral crystals of **potassium tribromomercuriate**, $\text{HgBr}_2 \cdot \text{KBr}$, or KHgBr_3 , were prepared by C. Löwig by evaporating a moderately conc. soln. of potassium bromide sat. with mercuric bromide. F. W. Clarke gave the sp. gr. as 4.412 (17.2°), 4.419 (24.5°), and 4.3996 (20.5°). According to M. Berthelot, the heat of formation for the crystalline double salt is 3.1 Cals., for the soln. at 8° , 2.75 Cals., and for the heat of soln., -8.9 Cals. The crystals melt when heated, and at a higher temp. furnish a sublimate of mercuric bromide and a residue of potassium bromide. Water precipitates half the combined potassium bromide. P. A. von Bonsdorff prepared crystals of **hydrated potassium tribromomercuriate**, $\text{HgBr}_2 \cdot \text{KBr} \cdot \text{H}_2\text{O}$, or $\text{KHgBr}_3 \cdot \text{H}_2\text{O}$, which F. W. Clarke found to have a sp. gr. 3.865 (20° - 24°), and M. Berthelot, a heat of formation of 6.4 Cals., and a heat of soln. of -2.2 Cals. T. Harth prepared long needle-like crystals of **potassium dibromodichloromercuriate**, $\text{HgBr}_2 \cdot 2\text{KCl}$, by crystallization from a mixed soln. of mercuric bromide and potassium chloride or potassium bromide and mercuric chloride in eq. proportions. T. Harth found the salt to be soluble in water, and at the same time to be decomposed with the separation of mercuric bromide if insufficient water is present to dissolve the latter. Ether also extracts mercuric bromide from the aq. soln. The electrical conductivity of the aq. soln. has also been measured.

H. L. Wells has prepared a series of cæsium bromomercuriates, and chlorobromomercuriates, and S. L. Penfield has measured the crystallographic constants. The ratio $\text{HgBr}_2 : \text{CsBr}$ is 1 : 3, 1 : 2, 1 : 1, and 2 : 1. All the salts are white excepting

the 1 : 1 salt, which has a lemon-yellow colour in spite of the fact that the constituents are both white. All the salts when recrystallized one or more times from water, yield the 2 : 1 salt, **cæsium pentabromodimercuriate**, CsHg_2Br_5 , or $2\text{HgBr}_2 \cdot \text{CsBr}$, with the chlorides, the 1 : 1 salt is the stable form with water. If alcohol be used for the recrystallization of the double bromide, then the 1 : 1 salt is the stable form. The crystals of the 2 : 1 salt are rhombic pseudohexagonal plates with axial ratios $a : b : c = 0.590 : 1 : 1.15$. The solubility in water is 0.807 per cent. at 16° ; the salt is sparingly soluble in hot alcohol and furnishes what are probably monoclinic crystals of CsHgBr_3 ; under similar conditions, the cubic form of CsHgCl_3 crystallizes from alcoholic soln. Cubic crystals of the 1 : 1 salt, **cæsium tribromomercuriate**, CsHgBr_3 , are formed as in the analogous case of the chloro-salt, when an excess of the cæsium halides is present, and a dimorphous variety in monoclinic crystals with axial ratios $a : b : c = 1.0124 : 1 : 0.70715$, and $\beta = 87^\circ 7'$ is deposited when the halide is not present in the soln. in so great an excess. Unlike the corresponding chloride, the second form of this salt is decomposed by crystallization from water and the 2 : 1 salt is formed, but if the latter be recrystallized from alcohol the monoclinic form of the 1 : 1 salt is obtained. The general appearance and mode of preparation of the 1 : 2 salt, **cæsium tetrabromomercuriate**, Cs_2HgBr_4 , or $2\text{CsBr} \cdot \text{HgBr}_2$, is exactly like the corresponding chloride. The rhombic bipyramidal crystals have the axial ratios $a : b : c = 0.5706 : 1 : 1.4715$; and, according to E. von Fedoroff, they are isotectic with those of potassium sulphate, K_2SO_4 , potassium tetrafluoberyllate, K_2BeF_4 , and potassium tetrachlorozincate, K_2ZnCl_4 . The 1 : 3 salt, **cæsium pentabromomercuriate**, Cs_3HgBr_5 , or $\text{HgBr}_2 \cdot 3\text{CsBr}$, is prepared exactly like the corresponding chloride and the slender prismatic crystals belong to the rhombic system, and have the axial ratios $a : b : c = 0.7966 : 1 : 0.6656$. They are isomorphous with the corresponding chloride.

H. L. Wells also prepared double compounds of cæsium chloride and mercuric bromide; and although the two salts unite together quite readily, there is a general tendency to form unmixed salts—all the chlorobromides finally yield mercuric bromide when recrystallized from water. All the chlorobromides are colourless excepting the pale yellow CsHgClBr_2 . The representative of the 1 : 3 type, **cæsium trichlorodibromomercuriate**, $\text{Cs}_3\text{HgCl}_3\text{Br}_2$, or $\text{HgBr}_2 \cdot 3\text{CsCl}$, is obtained from mixed soln. with a large excess of cæsium chloride. It forms slender prisms with axial ratios $a : b : c = 0.7882 : 1 : 0.6527$. The representative of the 1 : 2 type, **cæsium dichlorodibromomercuriate**, $\text{CsHgBr}_2\text{Cl}_2$, or $\text{HgBr}_2 \cdot 2\text{CsCl}$, is also formed when a large excess of cæsium chloride is present. The thin rectangular plates are rhombic bipyramids with axial ratios $a : b : c = 0.567 : 1 : -$. The representative of the 1 : 1 salt, **cæsium chlorodibromomercuriate**, CsHgClBr_2 , or $\text{HgBr}_2 \cdot \text{CsCl}$, forms pale yellow dimorphous crystals—cubic and rhombic with axial ratios approximately the same as the corresponding chloro-salt. It is possible that mixed crystals of the 1 : 1 chloro- and bromo-salts are in question. The 2 : 1 salt, **cæsium chlorotetrabromodimercuriate**, $2\text{HgBr}_2 \cdot \text{CsCl}$, or $\text{CsHg}_2\text{ClBr}_4$, forms rectangular plates belonging to the rhombic system with axial ratios $a : b : c = 0.586 : 1 : -$. When this salt is recrystallized from water, it furnishes crystals of **cæsium chlorodecabromopentamercuriate**, $\text{CsHg}_5\text{ClBr}_{10}$, $5\text{HgBr}_2 \cdot \text{CsCl}$, belonging to the monoclinic system with axial ratios $a : b : c = 0.7111 : 1 : 0.4561$, and $\beta = 85^\circ 29'$. These crystals are strongly double refracting.

A. Mailhe obtained a green **cupric mercuric oxybromide**, $\text{CuO} \cdot \text{HgBr}_2 \cdot 3\text{H}_2\text{O}$, by the action of a soln. of cupric bromide on mercuric oxide; and also a blue powder, $3\text{CuO} \cdot \text{CuBr}_2 \cdot 2\text{HgBr}_2 \cdot \text{H}_2\text{O}$, by the action of a soln. of cupric bromide on yellow mercuric oxide. A. Werner represented the latter by the formula :

W. Herz and W. Paul measured the solubility of mercuric bromide in soln. of calcium bromide and found the solubility increased *pari passu* with increasing

proportions of calcium bromide. At 25°, expressing conc. in milligram-mols in 10 c.c. of soln. :

CaBr ₂ . . .	0	0.72	6.45	18.92	24.79	37.54
HgBr ₂ . . .	0.17	1.17	6.76	13.58	27.66	36.66

P. A. von Bonsdorff found that when an aq. soln. of calcium bromide is sat. with mercuric bromide, and then evaporated, it (i) yields lustrous octahedral and tetrahedral crystals which are permanent in air, and decompose when treated with a small proportion of water. The crystals dissolve completely on the application of heat, and crystallize out again on cooling. (ii) When the mother liquid remaining after the separation of the first crop of crystals is further evaporated, it yields prismatic or acicular crystals which deliquesce rapidly even in dry air, and which contain a smaller proportion of mercuric bromide than the preceding salt. R. Varet found the heat formation of **calcium tetrabromomercuriate**, CaHgBr_4 , to be 2.82 Cals., and of **calcium hexabromodimercuriate**, $2\text{HgBr}_2 \cdot \text{CaBr}_2$, or CaHg_2Br_6 , 3.10 Cals., when the component salts are mixed in aq. soln. at 17°. C. Löwig prepared **strontium hexabromodimercuriate**, SrHg_2Br_6 , or $2\text{HgBr}_2 \cdot \text{SrBr}_2$, by dissolving three mols of mercuric bromide in a soln. of a mol of strontium bromide in twice its weight of water at 50°. When the soln. cools, it deposits a mol of mercuric bromide, and the mother liquid, when evaporated, yields crystals of the salt in question. When digested with water, C. Löwig found the mercuric bromide remains undissolved, and the liquid furnishes crystals of **strontium tetrabromomercuriate**, SrHgBr_4 , or $\text{HgBr}_2 \cdot \text{SrBr}_2$, on evaporation. R. Varet found the heat of formation of $2\text{HgBr}_2 \cdot \text{SrBr}_2$ from soln. of the component salts at 17° to be 3.06 Cals., and of $\text{HgBr}_2 \cdot \text{SrBr}_2$, 2.68 Cals. The 1 : 1 salt is soluble in all proportions of water. W. Herz and W. Paul measured the solubility of mercuric bromide in soln. of strontium and of barium bromides. P. A. von Bonsdorff prepared lustrous prismatic crystals of barium bromomercuriate. R. Varet gives the heat of formation of **barium hexabromodimercuriate**, $2\text{HgBr}_2 \cdot \text{BaBr}_2$, or BaHg_2Br_6 , prepared by mixing soln. of the component salts at 17°, as 3.17 Cals., and for **barium tetrabromomercuriate**, $\text{HgBr}_2 \cdot \text{BaBr}_2$, or BaHgBr_4 , 2.91 Cals.

P. A. von Bonsdorff evaporated a mixed soln. of magnesium and mercuric bromides over sulphuric acid, and the first crop of crystals which separate as broad plates were thought to be **magnesium hexabromodimercuriate**, MgHg_2Br_6 , or $2\text{HgBr}_2 \cdot \text{MgBr}_2$; and the second crop of deliquescent crystals, **magnesium tetrabromomercuriate**, MgHgBr_4 , or $\text{HgBr}_2 \cdot \text{MgBr}_2$. F. Calzolari and U. Tagliavini prepared crystals of a complex of $\text{MgBr}_2 \cdot 2\text{HgBr}_2 \cdot 10\text{H}_2\text{O}$ with hexamethylenetetramine. R. Varet gives 3.07 Cals. for the heat of formation of the former by mixing soln. of the component salts at 17°; and 2.8 Cals. for the latter. W. Herz and W. Paul have measured the solubility of mercuric bromide in soln. of magnesium bromide at 25°. P. A. von Bonsdorff also prepared prisms and plates of the double bromide of zinc and mercury which are permanent in dry air, and deliquescent in moist air—they are probably ZnHgBr_4 . By mixing soln. of the component salts at 17°, R. Varet found the heat of formation of **zinc hexabromodimercuriate**, $2\text{HgBr}_2 \cdot \text{ZnBr}_2$, or ZnHg_2Br_6 , to be 2.82 Cals., and of **zinc tetrabromomercuriate**, $\text{HgBr}_2 \cdot \text{ZnBr}_2$, or ZnHgBr_4 , 2.56 Cals. A. Mailhe prepared white monoclinic prisms and hexagonal plates of **zinc oxybromomercuriate**, $\text{ZnO} \cdot \text{HgBr}_2 \cdot 8\text{H}_2\text{O}$, by digesting mercuric oxide with a soln. of zinc bromide. Prismatic needles of the corresponding **cadmium oxybromomercuriate**, $\text{CdO} \cdot \text{HgBr}_2 \cdot 8\text{H}_2\text{O}$, were also prepared. R. Varet gives 2.2 Cals. for the heat of formation of **cadmium hexabromodimercuriate**, $2\text{HgBr}_2 \cdot \text{CdBr}_2$, or CdHg_2Br_6 , by mixing aq. soln. of the component salts at 17°; and for **cadmium tetrabromomercuriate**, $\text{HgBr}_2 \cdot \text{CdBr}_2$, or CdHgBr_4 , 2.44 Cals. C. Sandonnini studied the f.p. curve of mixtures of mercuric and lead bromides. There is a eutectic at 232°, with five mols per cent. of lead bromide, but there is no sign of the formation of *lead bromomercuriates*.

§ 23. Mercurous Iodide

Mercury forms two iodides—mercurous iodide, HgI ; and mercuric iodide, HgI_2 . The two elements unite together at ordinary temp., and, according to W. A. Shenstone,¹ the reaction occurs only if moisture be rigorously excluded. A mixture of the two iodides is formed by triturating the two elements together, and A. R. von Schrötter noted that if mercury be placed in a dish, and iodine or a sat. soln. of iodine in potassium iodide be placed in another dish, and both be confined under a jar, the mercury becomes dark violet and finally changes to red mercuric iodide. According to C. Brame, if mercury and iodine are placed in different parts of a tube, the mercury iodide is formed at a distance away from both elements, showing that combination probably takes place between their vapours. According to H. Gautier and G. Charpy, the reaction between mercury and an aq. or alcoholic soln. of iodine is fairly rapid. According to M. Berthelot, hydrogen iodide reacts fairly quickly with mercury, and G. H. Bailey and G. J. Fowler noted the reaction occurs in the absence of oxygen. Green mercurous iodide is first formed very rapidly, and this is converted by an excess of hydrogen iodide into red mercuric iodide. The mercuric iodide is reconverted to mercurous iodide if an excess of mercury be added. Mercury is decomposed by aq. hydriodic acid more readily than by hydrobromic acid.

The preparation of mercurous iodide.—(1) *From mercury and iodine.*—Mercurous iodide was made by J. B. Berthelot² by triturating equi-grammolar proportions of the two elements—preferably moistened with alcohol. The iodine is dissolved by the alcohol and quickly transferred to the mercury. According to E. Siller, much heat is evolved during the trituration, the mass liquefies, and iodine vapour is given off. On cooling, a reddish-brown mass is produced; if this be ground with alcohol, a greenish-yellow powder is obtained. The product is always contaminated with a little mercuric iodide; and L. Mailhe showed that even if a less than an equimolar proportion of iodine be employed, some mercuric iodide is produced during the action. The mercuric iodide can be removed by leaching the product with alcohol, and E. Soubeiran recommended washing out the mercuric iodide with boiling alcohol. He found that some mercuric iodide is extracted even when the mercury has been rubbed up with but half its weight of iodine. The product must then contain some free mercury. F. R. Williams recommended extracting the mercuric iodide with a soln. of sodium chloride; and M. François, with cold ether. E. Riegel failed to obtain products of a constant composition by the trituration process. When mercury is agitated with a soln. of iodine, mercurous iodide is formed, but if other metals be present the iodide of that metal may be formed

before the mercury is attacked. Thus, H. Gautier and G. Charpy found this to be the case when lead amalgam is shaken up with a brown soln. of iodine in alcohol, ether, or acetone. Yellow lead iodide is first formed and the mass then becomes green owing to the formation of mercurous iodide; they also say that violet soln. of iodine in carbon disulphide or chloroform gives green mercurous iodide just as would be the case if lead were absent. They explain the action by assuming that the mercuric iodide first formed is transformed by the lead into mercurous iodide, and mercuric iodide is regenerated by the excess of iodine. According to E. Beckmann and A. Stock, the action rests on the difference in the solubility of the mercuric iodide—in alcoholic soln. the mercuric iodide is reduced by lead, but it is precipitated by chloroform as finely divided mercury and mercurous iodide which reacts with difficulty with the lead. If water be used instead of alcohol for the trituration the mercury and iodine combine more slowly, but the reaction is quicker if the mixture be heated; the product of the trituration with water is brownish-red, and with alcohol yellowish-green. M. François treated mercury with a soln. of iodine in *N*-KI, saturated at 20°, forming mercurous iodide until the soln. has 11.9 grms. of mercuric iodide per 100 c.c. at 20°. Nessler's reagent also attacks mercury with the formation of mercurous iodide. According to H. Fleck, mercurous iodide is formed by the action of aluminium amalgam on ethyl iodide; P. Yvon heated a mixture of equimolar proportions of the component elements in a retort to a temp. not exceeding 250°. Mercurous iodide sublimes in red crystals, which become yellow when cold. According to A. Stroman, the product is impure.

(2) *From mercurous salts and iodine or iodides.*—A. Stroman boiled a sat. soln. of mercurous nitrate, feebly acidified with nitric acid—and as free as possible from mercuric salts—along with an excess of iodine; he poured the hot clear liquid into a vessel previously warmed, and cooled it in darkness. The liquid was filtered in darkness, and the mercurous iodide was washed with nitric acid, then with water, and finally dried in darkness at room temp. on filter paper frequently renewed. A. Stroman also used an alcoholic soln. of iodine under similar circumstances. N. E. Henry, and J. B. Berthemot decomposed mercurous nitrate, or chloride with hydriodic acid, or better, with potassium iodide. Since mercurous nitrate requires an excess of nitric acid for its soln. in water, this excess remains free—unless the potassium iodide contains hydroxide or carbonate as recommended by N. E. Henry to neutralize the excess of acid and avoid the formation of mercuric iodide—and an oxidizing action will set in converting mercurous to mercuric iodide; hence, the liquid should be rapidly filtered. The oxidation is more rapid when hydriodic acid is employed than when potassium iodide is used. If the mercurous nitrate is contaminated with mercuric nitrate, mercuric iodide will be formed. If an excess of potassium iodide be used, mercurous iodide will be converted into mercuric iodide which dissolves, and metallic mercury which remains mixed with the precipitate; but a slight excess of potassium iodide is useful in dissolving the mercuric iodide formed by the nitric acid. C. Soetje, R. Varet, and M. François used a similar process. According to M. François, a soln. of mercurous nitrate transforms mercuric iodide into mercurous iodide, and nitric acid dissolves any finely divided mercury which may be present. Hence, he recommends the following preparation:

Dissolve 125 grms. of mercurous nitrate in 2 litres of water containing 20 grms. of nitric acid; and add a soln. of 50 grms. of potassium iodide in 100 grms. of water, drop by drop, with vigorous agitation. Each drop produces a grey stain which soon becomes yellow. The liquid is agitated 3 or 4 times, while it is allowed to stand 24 hrs. and then decanted from the precipitate, which is then well washed. It is not advisable to wash with alcohol because this liquid decomposes mercurous iodide into the mercuric salt and mercury.

M. François also recommended a soln. of iodine in potassium iodide; F. Bodroux, methyl or ethyl iodide; and P. F. G. Boullay, ferrous iodide. P. C. Ray obtained mercurous iodide as a by-product in the action of ethyl iodide on mercurous nitrite at 190°–210°. Mercurous acetate was used by P. F. G. Boullay in place of the

nitrate, but mercurous acetate is but sparingly soluble in cold water, and it is decomposed by hot water into soluble mercuric acetate and mercury. J. B. Berthémot, therefore, pointed out that it is best to triturate solid mercurous acetate in the cold with an aq. soln. of potassium iodide. A greenish-black powder is first produced, but this soon becomes yellowish-green. The product is liable to be contaminated with undecomposed mercurous acetate which cannot be extracted by cold water, and is resolved by hot water into soluble mercuric acetate and metallic mercury, which remains mixed with the mercurous iodide. J. Lefort recommended a soln. of one part of mercurous acetate, and two parts of sodium pyrophosphate in 10 parts of warm water in place of a soln. of mercurous acetate alone. The mercurous iodide was precipitated by the addition of a soln. of one part of potassium iodide. J. Inglis recommended triturating 235.4 parts of mercurous chloride with an aq. soln. of 165.2 parts of potassium iodide; if the mercurous chloride be in excess, it remains undecomposed; and leads to the separation of metallic mercury. O. Lichtenberg said that the product is contaminated with mercurous chloride and mercury.

(3) *From mercuric iodide*.—J. B. Berthémot prepared mercurous iodide by triturating 226 parts of mercuric iodide with 100.6 parts of mercury—preferably with the addition of a little alcohol. T. Rieckher used a similar process. M. François claimed that mercurous iodide of a very high degree of purity can be made by the following process:

Dissolve 50 grms. of mercuric iodide in a heated mixture of 100 grms. of aniline and 20 grms. of alcohol. Crystals of diphenyldimercuriammonium iodide are deposited on cooling. On adding ether to the mother liquid, acicular greenish-yellow crystals of mercurous iodide are deposited. The preparation depends on the reducing action of a small amount of aldehyde present in ether—for a soln. of aldehyde in 1000 parts of alcohol precipitates mercurous iodide from a soln. of mercuric iodide in aniline.

B. D. Steele noticed the formation of mercurous iodide when a soln. of potassium iodide in liquid sulphur dioxide is electrolyzed using a mercury anode. J. W. Clark prepared mercurous iodide by the electrolysis of molten mercuric iodide with graphite electrodes.

A. Lottermoser prepared *colloidal mercurous iodide* by the action of iodine water on colloidal mercury. According to the patented process of the Chemische Fabrik von Heyden, 20 parts of albumen albuminose peptone, or white of egg, are dissolved in 500 parts of water, and added to a soln. of 17 parts of potassium iodide in 100 parts of water, and the mixture is then stirred with 26 parts of mercurous nitrate in 2000 parts of water, and the yellow soln. dialyzed. The greenish-yellow powder is soluble in water, forming a neutral yellowish-green soln. It is precipitated from the aq. soln. by alcohol, acetone, or acids. The precipitate by alcohol or acetone is directly soluble in water, but the precipitate by acids requires neutralization with an alkali before it is soluble. J. Hausmann has studied the precipitation of mercurous iodide in the presence of gelatine.

The properties of mercurous iodide.—The older chemists—J. Inglis, P. F. G. Boulay, J. B. Berthémot, etc.—described the **colour** of mercurous iodide as yellowish-green or green, and later, when yellow varieties were prepared, R. Varet³ suggested that this compound occurs in two allotropic states—yellow and green—and he actually measured what he regarded as the heat of transformation from the green to the yellow—0.15 Cal. M. François says that purified mercurous iodide is as yellow as lead chromate, the green colour appears only when very finely divided mercury is present; the green colour is the resultant effect of the superposition of the colour of mercury on that of mercurous iodide. This is shown by the variations in the tint with different modes of preparation; analyses of the green specimens show an excess of mercury over that required for mercurous iodide; the purer the specimen the more it inclines to yellow; the yellow samples can be made green by charging them with finely divided mercury—say by adding a little potassium mercurous iodide; and the green specimens can be made yellow by

dissolving out the mercury—with dil. nitric acid; or by converting the mercury into mercurous iodide by digesting it with a soln. of iodine in potassium iodide. The fact that the properties attributed to mercurous iodide by the older chemists really referred to a mixture of that salt contaminated with a little finely divided mercury renders it necessary to accept many of their statements with some reserve.

According to A. des Cloizeaux, the **crystals** obtained by sublimation are tetragonal (P. Yvon said rhombic) plates with the axial ratio $a : c = 1 : 1.6726$ probably, and isomorphous with the crystals of mercurous chloride. According to E. J. Houston, when the light yellow salt is heated, it gradually darkens as the temp. rises, becoming dark yellow, orange, and orange-red; and on cooling these colours appear in the reverse order; at 100° , A. Stroman said that the salt is always yellow. In sodium light, P. Yvon found the pale green colour changed to red at 70° , and at 220° , garnet red. B. Gossner obtained a specimen of mercurous iodide, by the trituration of mercuric iodide and mercury, which turned red abruptly when heated. It is, therefore, assumed that the red form is stable at the higher temp., the yellow at ordinary temp.; that the salt is dimorphous; and that the tetragonal form of the crystals is retained as the salt passes into the yellow modification. According to C. J. B. Karsten, the **specific gravity** is 7.6445; and, according to P. F. G. Boullay, 7.75.

The crystals sublime when heated, and, according to A. Stroman,⁴ the sublimation begins between 110° and 120° (P. Yvon says 190°), and increases in velocity with rise of temp.; P. Yvon says the crystals melt to a black liquid, the **melting point** being 290° , with partial decomposition, and the **boiling point** is about 310° . L. Troost measured the **vapour density** between 752 and 754 mm., and found a mean value 15.2—the theoretical value is 15.7. The mol. wt. calculated by E. Beckmann from the depression of the f.p. of molten mercuric iodide agrees with Hg_2I_2 , H. V. Regnault's value for the **specific heat** between 17° and 99° is 0.0395; and E. Goldstein gives for the **molecular heat** 6.4.

The **heat of formation** from solid mercury and iodine is (Hg, I) 23.8 Cals., according to M. Berthelot;⁵ 24.22 Cals., according to J. Thomsen; and from liquid mercury and solid iodine, according to R. Varet, 28.85 Cals. for the yellow amorphous solid; 28.55 Cals. for the greenish-yellow; and for the yellow salt from liquid mercury and solid yellow mercuric iodide, 6.65 Cals. The **free energy** of formation at 18° is -26.8 Cals. calculated by M. de K. Thompson. J. Thomsen also gives $(\text{HgNO}_3)_{\text{aq.}}, (\text{KI})_{\text{aq.}} = 21.26$ Cals.; $(\text{Hg}_2\text{O}, 2\text{HI})_{\text{gas.}}, 86.68$ Cals.; and R. Varet, $\text{Hg}_2\text{O}_{\text{precipitated}} + 2\text{HI}_{\text{soln.}} = 2\text{HgI}_{\text{yellow}} + 49.25$ Cals.

A. des Cloizeaux⁶ reported that mercurous iodide crystals exhibit a strong positive double refraction, and J. A. Wilkinson found the salt exhibits a reddish-brown or orange fluorescence. A. L. Hughes has studied the photo-electric effect. S. Bugarszky measured the free energy of the reaction: $2\text{HgCl}_{\text{solid}} + 2\text{KI}_{\text{soln.}} = 2\text{HgI}_{\text{yellow}} + 2\text{KCl}_{\text{soln.}}$, from the e.m.f. of the cell $\text{Hg} \mid \text{Hg}_2\text{Cl}_2, \frac{1}{100}N\text{-KCl} \mid N\text{-KNO}_3 \mid \frac{1}{100}N\text{-KI}, \text{Hg}_2\text{I}_{2\text{yellow}} \mid \text{Hg}$, and found for temp. 0° , 18.5° and 43.4° , the respective values $\epsilon = 0.3131, 0.3086$, and 0.3117 volt; $d\epsilon/dT = -0.00027$. The free energy is therefore 7134 cal., the bound energy 1819 cal., the total energy 8953 cal.; and the observed value of $Q = 9310$ cal. For the free energy of the reaction: $2\text{HgCl}_{\text{solid}} + 2\text{KI}_{\text{soln.}} = 2\text{HgI}_{\text{greenish-yellow}} + 2\text{KCl}_{\text{soln.}}$, from the e.m.f. of a similar cell with greenish-yellow mercurous iodide substituted in place of the yellow salt, for temp. 0° , 18.5° , and 43.3° , the respective values $\epsilon = 0.3131, 0.3083$, and 0.3017 volt; $d\epsilon/dT = -0.000265$. The free energy is therefore 7127 cal., the bound energy 1786 cal., the total energy 8913 cal., and the observed value of Q , 9160 cal. Hence, owing to the agreement between the free and bound energies with the yellow and greenish-yellow salts, it is inferred that these two forms of mercurous iodide are *chemisch identisch*. S. Bugarszky also gives for the energy of the reaction: $\text{Hg}_2(\text{C}_2\text{H}_3\text{O}_2)_{2\text{solid}} + 2\text{KI}_{\text{soln.}} = \text{Hg}_2\text{I}_{2\text{yellow}} + 2\text{K}(\text{C}_2\text{H}_3\text{O}_2)_{\text{soln.}}$, calculated from the cell $\text{Hg} \mid \text{Hg}_2(\text{C}_2\text{H}_3\text{O}_2)_2, N\text{-KC}_2\text{H}_3\text{O}_2 \mid N\text{-KC}_2\text{H}_3\text{O}_2 \mid \frac{1}{100}N\text{-KOH}, \text{Hg}_2\text{O} \mid \text{Hg}$, where he found for 0° and 18.5° the respective values $\epsilon = 0.4498$ and

0.4277 volt; and $d\epsilon/dT = -0.00118$, the following values: free energy, 9883 cal.; bound energy, 7951 cal.; total energy, 17834 cal.; and Q observed = 17,275 cal. F. Braun estimates that 41 to 50 per cent. of the heat of formation can be transformed into electrical energy.

R. Varet⁷ says that highly purified mercurous iodide is very little changed when kept away from light; but, according to W. Artus, when mercurous iodide is exposed to **light**, it becomes dark green and finally black, but these changes occur only if the compound is moist, and he adds that no free iodine is then evolved, but hydrogen iodide is given off, and therefore mercurous oxide is probably formed; and, according to J. Inglis, when kept a few weeks in vessels containing air, in darkness, mercury and mercuric iodide are formed in dentritic excrescences—he adds that the decomposition, however, does not take place under water. J. M. Eder says that mercurous iodide blackens in light even if oxygen and moisture are excluded, and he wrongly supposed that mercurous iodide, Hg_2I_3 , is formed. P. Yvon exposed crystalline mercurous iodide for eight years in a flask closed by a sheet of paper, and found it had become almost black; the blackened iodide had lost 0.44 per cent. of mercury; and some crystals of red mercuric iodide collected in the upper part of the flask. A. Stroman found that the precipitated salt is more sensitive to light than the crystalline salt.

A. Mailfert found **ozone** converted mercurous iodide into an oxyiodide. By heating a mixture of mercuric oxide and mercurous iodide obtained by dropping alcoholic potassium hydroxide into a boiling alcoholic soln. of mercuric iodide, with water in a sealed tube at 160° for 80 hrs., and floating off the unchanged mercuric oxide and mercurous iodide, T. Fischer and H. von Wartenberg prepared brownish-red rhombic plates of **tetramercurous trioxiodide**, $3HgO \cdot HgI$, which, when heated in an open tube and when treated with acids or alkalies, behaves like a mixture of the primary constituents.

According to F. Labouré, when mercurous iodide is sublimed it is resolved into metallic mercury which collects at the top, and a greenish-yellow sublimate below—he wrongly supposed that mercurous iodide, Hg_2I_3 , is formed; P. Yvon says that when heated very quickly an oxyiodide, $6HgO \cdot 7HgI_2$, sublimes; while A. Stroman, and M. François say that mercurous iodide cannot be melted without decomposition, and that a mixture of mercury and mercuric iodide is formed as a sublimate, leaving a residue of mercurous iodide. M. François found that mercuric and mercurous iodides in the mol. proportions 2 : 1 can be melted without decomposition.

According to M. Saladin,⁸ 100 c.c. of **water** dissolve less than 0.042 gm. of mercurous iodide. G. Bodländer estimates the solubility to be 2.6×10^{-8} ; M. S. Sherrill, 3×10^{-10} ; and J. F. Spencer, 3×10^{-3} . There is probably some hydrolysis of the iodide, the solubility product $[Hg_2^{2+}][I_2']$ is 1.2×10^{-28} . According to S. Schlesinger, concentrated **nitric acid** decomposes it into mercuric iodide and nitrate which crystallize as a double salt or mixed crystals on cooling. M. François found a soln. of **mercuric nitrate** enters into a reversible reaction, forming mercurous nitrate and mercuric iodide, $Hg(NO_3)_2 + 2HgI \rightleftharpoons 2HgNO_3 + HgI_2$. According to E. Riegel, **sulphuric acid** at ordinary temp. has no action, but, according to A. Souville, when heated it forms a double salt, $HgSO_4 \cdot HgI_2$; and he symbolizes the reaction: $2HgI + 2H_2SO_4 = HgI_2 \cdot HgSO_4 + SO_2 + 2H_2O$. Hydrogen chloride was found by P. Hautefeuille to decompose mercurous iodide but slightly if heated below the sublimation temp., while boiling hydrochloric acid slowly forms mercuric chloride and mercury; according to E. Esteve, **hydrocyanic acid** first transforms mercurous iodide into mercuric cyanide, liberating hydriodic acid: $2HgI + 2HCy = HgCy_2 + 2HI + Hg$; the hydriodic acid then reacts with the liberated mercury reforming mercurous iodide. P. F. G. Boullay found that a boiling soln. of **ammonium or sodium chloride** dissolves a little mercuric iodide, and a little mercury separates—L. Mailhe says the mercurous iodide is converted into mercuric chloride which dissolves. P. F. G. Boullay and F. Labouré found that hydriodic

acid or an aq. soln. of a **soluble iodide**—e.g. potassium sodium, barium, calcium, magnesium, or zinc iodide—forms soluble mercuric iodide and metallic mercury. A. Stroman noted that **potassium iodide** colours mercurous iodide green in the cold, and black when heated; but, according to M. François, a dil. soln. of potassium iodide changes the green colour to yellow, $2\text{HgI} + 2\text{KI} \rightleftharpoons \text{HgI}_2 \cdot 2\text{KI} + \text{Hg}$; the reaction is reversible; similarly, with hydriodic acid, but if the acid be concentrated, there is a violent reaction between the hydriodic acid and the mercury formed in the early stages of the reaction. No gas is evolved if the hydriodic acid be dil. more than 97.14 grms. per 100 c.c. of liquid and there is a reversible reaction: $2\text{HgI} + \text{HI}_{\text{aq.}} \rightleftharpoons \text{HgI}_2 + \text{Hg} + \text{HI}_{\text{aq.}}$. The hydriodic acid dissolves mercuric iodide and the soln. attacks the liberated mercury. For equilibrium, 100 c.c. of liquid contain in grams:

HI	. 1.142	2.214	4.062	8.272	16.167	28.682	49.807	67.099
HgI ₂	. 0.3405	1.2485	3.518	8.853	20.815	47.670	91.559	118.720

F. Jander found mercurous iodide is more soluble in soln. of **ammonium iodide** than in water—if S_0 be the solubility in water, and S the solubility in a soln. of ammonium iodide with 0.1, 0.25, 0.5, and 1.0 mol per litre, $S - S_0$ is respectively 0.0492, 0.131, 0.236, and 0.549, and the ratio of the conc. of ammonium chloride to $(S - S_0)$ lies between 1.8 and 2.0. It is thought that the soln. contains the complex $\text{HgI}_2\text{NH}_2\text{I}$ or NH_4HgI_3 . Similar results were obtained with soln. of potassium iodide by R. Abegg and F. Jander. According to M. François, 20 c.c. of a normal soln. of potassium iodide with 6.54 grms. of potassium iodide are in equilibrium when the soln. has 2.38 grms. of mercuric iodide and the mercurous iodide becomes green; with 20 c.c. of the potassium iodide soln. and 2 grms. of mercurous iodide at 20°, all is converted into mercuric iodide and mercury. According to E. C. Franklin and C. A. Kraus, mercurous iodide is very easily soluble in liquid **ammonia**. G. C. Wittstein found it to dissolve in aqua ammonia, leaving a grey residue—probably globules of mercury; and M. François says that it transforms mercurous into mercuric iodide, and finally, according to H. Saha and K. N. Choudhuri, into white mercuric diammino-iodide, $\text{HgI}_2 \cdot 2\text{NH}_3$. M. François also noted that aqua ammonia or alkali-lye transforms mercurous iodide into a green mass, which then blackens, and the corresponding iodide of ammonium or alkali is formed. C. F. Rammelsberg obtained what he regarded as dimercuriammonium iodide, Hg_2NI , from the mother liquid remaining after aqua ammonia had been allowed to act on mercurous iodide. R. Behrend found that mercurous iodide is but slightly affected by dil. aqua ammonia, and he measured the e.m.f. of ammonia soln. in contact with this salt.

M. Saladin said that mercurous iodide is insoluble in *ethyl alcohol*; H. MacLagan says it is not quite insoluble therein, and M. François says that boiling alcohol forms mercury and mercuric iodide until there is present 0.220 grm. of mercuric iodide per 100 grms. of alcohol when the system is in equilibrium, for the reaction is reversible. H. Saha and K. N. Choudhuri report that *methyl alcohol* forms no mercuric iodide. Unlike mercuric iodide, says M. François, mercurous iodide is insoluble in cold *ether*, but H. MacLagan adds that it is not completely insoluble in this menstruum. Mercurous iodide is slightly decomposed by *chloroform*. J. H. Mathews found the specific conductivity of a sat. soln. of mercurous iodide in *allyl mustard oil* to be 4.3×10^{-5} at 25°. J. W. Retgers says mercurous iodide is virtually insoluble in *methylene iodide*. M. François found that mercurous iodide is decomposed by *phenol*, with which it reacts reversibly; similar remarks apply to *aniline*.

§ 24. Mercuric Iodide

Mercuric iodide exists in two forms—red and yellow. It occurs in nature as the mineral *coccinite*, reported by A. del Rio¹ in reddish-brown particles in some mercury ores at Cases Viejas (Mexico), but A. del Castillo has stated that the specimens labelled by A. del Rio contained no iodine. There is, therefore, some doubt about this mineral. J. Domeyko described some *minerales de plata clorodurados mercuriales* from Caraceles (Chili) with 10.5 to 13.96 per cent. of iodine; 5.3 to 13.65 per cent. chlorine; 9.2 to 20.5 per cent. of mercury; and 16.9 to 40.65 per cent. of silver.

The preparation of mercuric iodide.—B. Courtois² prepared vermilion-coloured mercuric iodide by agitating the two elements together in the cold. L. N. Vauquelin made it by triturating the two elements moistened with a little water.

J. B. Berthelot made mercuric iodide by triturating together mercury and iodine in atomic proportions, $\text{Hg} : \text{I} = 1 : 2$. According to F. Mohr, the combination is not complete because free iodine and mercurous iodide are formed. The union is more complete if water or alcohol be present; if too much alcohol be employed, the temp. rises, the mass fuses, and some iodine is evaporated. J. B. Dublanc recommended pouring a kgrm. of alcohol on 100 grms. of mercury; adding 124 grms. of iodine in successive portions of 10 grms.; and agitating the mixture after each addition until the alcohol becomes colourless. The alcohol remains coloured after the last addition of iodine because all the mercury is then converted into mercuric iodide. The red product is washed with alcohol and dried.

L. N. Vauquelin made the same salt by triturating iodine with mercurous oxide, mercurous nitrate, or mercuric nitrate—some iodate is said to be formed in the last-named reaction.

When a soln. of mercuric chloride, nitrate, or acetate is mixed with an aq. soln. of iodine, C. F. Schönbein noted that a peculiar compound with mercury is formed—possibly a hypoiodite—with the characteristic smell of iodine, and the reaction with starch no longer appears. E. Schaer observed a similar result with chlorine and bromine water.

X. Landerer used mercurous chloride; M. C. Schuyten, mercuric chloride; E. Soubeiran, mercurous iodide, or mercuric cyanide; and J. Schröder used mercury or a mercurous salt and washed the product with pyridine—mercurous sulphate and chromate do not react with the iodine satisfactorily. C. F. Rammelsberg boiled mercuric oxide with iodine and water. F. Gramp heated mercuric chloride with iodine in a sealed tube at 250° for 6 hrs.; E. Soubeiran heated mercurous iodide with arsenic iodide when the latter compound is reduced to arsenic. According to E. P. Perman, if the mercuric chloride and potassium iodide be finely powdered, and thoroughly dried over phosphorus pentoxide, the red coloration indicating the formation of mercuric iodide does not appear.

When mercury is treated with hydriodic acid, mercuric iodide is formed and hydrogen evolved; and, according to R. S. Norris and F. G. Cottrell, this more readily than is the case when mercuric bromide is formed by the action of hydrobromic acid on mercury. P. F. G. Boullay made mercuric iodide by precipitation from aq. soln. of mercuric nitrate or chloride with hydriodic acid, or a soln. of potassium or ferrous iodide and washing the product with water; he added that unless the materials are mixed in eq. proportions, part of the mercuric iodide remains dissolved either in the excess of mercuric salt or the potassium iodide.

H. Köhler also recommended suspending 10 grms. of iodine in water, and adding iron filings until all the iodine is changed to ferrous iodide; this soln. is immediately poured into one containing 10.75 parts of mercuric chloride. The precipitated mercuric iodide is rapidly separated from the mother liquid to avoid contamination with iron oxychlorides. The precipitate is washed with cold water and recrystallized by cooling a soln. of the salt from a hot soln. of potassium iodide or hydrochloric acid. The red lustrous crystals have a greenish reflection.

M. François treated mercury with a soln. of iodine and potassium iodide. F. R. Williams made mercuric iodide by precipitation from a soln. of four parts of mercuric chloride and two parts of ammonium chloride by five parts of potassium iodide. W. Sievers boiled a soln. of mercuric nitrate with iodine. C. F. Schlagdenhauffen heated mercuric chloride with ethyl iodide in a sealed tube at 100° ; F. Bodroux agitated an aq. soln. of mercuric acetate with methyl iodide for 12 hrs.; M. C. Schuyten exposed a mixture of mercuric chloride and methyl iodide in ethereal soln. to sunlight and found mercuric iodide was quantitatively precipitated. E. Rupp and S. Goy treated a soln. of mercuric oxide and cyanide with potassium iodide; and W. O. de Coninck treated a soln. of potassium chlorocyanomercuriate with butyl iodide. A. Ditte treated a conc. aq. soln. of iodic acid with mercury and found that the resulting mercuric iodide is mixed with some iodate. C. Fränkel recommended purifying the salt by recrystallization from a boiling soln. of conc.

hydrochloric acid, and washing the product with cold water. J. Preuss, and E. Riegel studied various methods of preparing this salt. A. Lottermoser prepared colloidal soln. of mercuric iodide by the action of a soln. of iodine on colloidal mercury; and J. Hausmann studied the formation of mercuric iodide in soln. of gelatine.

In 1827, P. F. G. Boullay³ described what he regarded as *un iodure de mercure intermédiaire*, formed by adding a soln. of potassium iodide or hydriodic acid to mercurous nitrate, and not collecting the precipitate until the colour has changed to yellow; and also by dissolving in a soln. of potassium iodide an amount of iodine eq. to half that contained in the salt, and adding the soln. to one of mercurous nitrate. The red precipitate first formed becomes yellow on agitation. If too much iodine soln. has been added, mercuric iodide is formed, and this may be removed by washing with alcohol. J. M. Eder also supposed this salt is formed by the action of light on moist mercurous iodide. J. L. Gay Lussac and J. J. Colin supposed the yellow product to be mercurous iodide, but J. Inglis, P. F. G. Boullay, etc., showed that it contains more iodine than mercurous iodide, and P. F. G. Boullay regarded it as *mercurous iodide*, Hg_2I_3 . M. François, however, showed that the product is really a mixture of mercurous and mercuric iodides which can be separated by extraction with ether.

The properties of mercuric iodide.—In 1833 E. Mitscherlich⁴ demonstrated that mercuric iodide exists in two allotropic forms—a red tetragonal form which is stable and is obtained by crystallization from soln. at ordinary temp.; and a yellow rhombic form which is not stable and is obtained by sublimation or by crystallization from the molten salt. According to W. C. Luczizky, the axial ratios of the yellow rhombic crystals are $a : b : c = 0.62688 : 1 : 1.7893$; and of the red tetragonal crystals $a : c = 1 : 2.0080$. E. Taubert, P. Groth, W. C. Luczizky, H. Köhler, E. Mitscherlich, and A. Oppenheim, have obtained ditetragonal bipyramidal crystals of different habits from hydrochloric acid, methyl and ethyl alcohols, acetone, allyl iodide, benzene, etc., and aq. soln. in presence of mercuric chloride or bromide, or potassium iodide. According to P. Groth, the crystals from benzene or potassium iodide soln. are normally uniaxial, but from acetone soln. the crystals are for the most part anomalous in appearing biaxial. J. H. Kastle found that at -190° the red variety becomes orange-yellow, and the red form is white. J. Dewar found that in liquid air, red mercuric iodide is yellow, and in liquid hydrogen white—the original colour returns when the atm. temp. is restored; D. Dobrosserdoff found that when cooled by solid carbon dioxide, red crystalline mercuric iodide becomes yellow, and he stated that the change is due neither to dissociation nor to modifications in the structure of the mol.

The yellow crystals obtained by sublimation may retain their yellow colour when cooled, or they may become scarlet-red. If the yellow colour is retained, the red colour is very quickly resumed when the crystals are mechanically agitated by rubbing, stirring, or scratching with a pointed instrument. The part so treated becomes scarlet, and, according to A. A. Hayes, "this change of colour extends with a slight motion throughout the whole mass of adherent crystals as if the mass were alive. During this change the crystals retain their form unchanged and are therefore pseudomorphic"; and R. Warington added that under the microscope the red coloration extends through the yellow plates by sudden starts, and is bounded by a line parallel to a lateral face or to a diagonal. C. Strzyzowsky has also examined the formation of mercuric iodide microscopically. W. W. Mather noted that the fused mass exhibits a red colour immediately after solidification, but very rapidly turns yellow. The same crystals turn yellow every time they are heated and red again on cooling. On cooling, however, the crystals may remain yellow for several days. W. Spring also noted that press. transforms yellow mercuric iodide into the red variety. G. Tammann prepared a colourless modification of mercuric iodide by heating mercuric iodide to 300° – 500° in a long glass tube connected with a receiver in which the press. can be suddenly reduced from one to one-tenth atm. The colourless snow-like mass so obtained becomes pink in a few seconds, and red after some minutes. If the receiver is cooled to

a low temp. the white form persists longer. Yellow mercuric iodide appears white if cooled to the temp. of liquid air, but this white form is not identical with the other.

A. Oppenheim first determined the **transition temperature** by heating the iodide in capillary tubes. He found 148° – 154° , and added that the result is dependent on the quantity of substance employed, and on the diameter of the capillary. He regarded 148° as the most probable value. H. Köhler gave 150° . W. Schwarz showed that the transition point is 126.3° ; G. F. Rodwell and D. Gernez gave 126° ; A. Smits, and A. Steger, 127° ; W. Reinders, 127.2° ; J. S. van Nest, and C. Sandonnini, 128° ; J. Guinchant, 130° ; and M. Padoa and C. Tibaldi, 131.9° . Consequently, at normal press., the yellow variety is stable above 128° , and the red form is stable below 128° . The red in general changes to the yellow form sharply on passing through 127° , but on cooling the yellow colour may persist for several hours, showing that the red form cannot be much superheated, but the yellow form can be considerably undercooled. The transformation from yellow to red mercuric iodide proceeds very quickly in presence of a crystal of the red variety. W. Schwarz noted that the transformation temp. is raised 1.1° by a press. of 100 atm. According to W. Reinders, the transition temp. is lowered by admixture with mercuric bromide as illustrated in Fig. 25; and, according to M. Padoa and C. Tibaldi, by admixture with mercuric chloride. A. Steger found the transition point is raised from 127° to 132° by silver iodide.

P. W. Bridgman studied the effect of press. on the transition point of mercuric iodide, and found that it rose to a maximum when the press. approximates to 5000

FIG. 24.—Effect of Pressure on the Transition Temperature of Mercuric Iodide.

kgms. per sq. cm. as illustrated in Fig. 24, and in Table X. The latter also shows the change in vol., δv in c.c. per gram in passing through the transition point; the change in the transition temp. per unit change of press. dT/dp ; the latent heat in kilogrammetres per gram; and the change of internal energy in kilogrammetres per gram.

According to W. C. Luczizky, light yellow crystals of approximately $\text{HgI}_2 + 2\text{HgBr}_2$ are obtained by slowly cooling a soln. of mercuric iodide in a warm sat. soln. of the bromide, the axial ratios of the crystals are $a:b:c = 0.6782:1:1.7878$; and from a soln. of $\text{HgI}_2 + 6\text{HgBr}_2$, crystals of the composition $\text{HgI}_2 \cdot 2\frac{1}{2}\text{HgBr}_2$ with axial ratios $a:b:c = 0.6718:1:1.7222$ are also formed. P. Groth found a mixture with approximately $\text{HgI}_2 + \text{HgBr}_2$ has the axial ratios $a:b:c = 0.6443:1:1.8389$. J. S. van Nest obtained an unbroken series of yellow mixed

TABLE X.—EFFECT OF PRESSURE ON THE TRANSITION POINT OF MERCURIC IODIDE.

crystals with up to 97 per cent. mercuric iodide; while if less than 3 per cent. of mercuric bromide be present, only red crystals are formed. Red mixed crystals can also be obtained with up to 50 per cent. mercuric iodide. W. Reinders and P. Niggli also obtained an unbroken series of yellow rhombic crystals by cooling molten mixtures of the two salts. The fusion curve corresponds with H. W. B. Roozeboom's curve Type III—mercuric bromide fuses at 236° , the iodide at 255° , and the minimum with about 41 per cent. of mercuric iodide at 216.7° .

FIG. 25.—Fusion Curves of Binary Mixtures of Mercury Bromide with Mercury Chloride and Iodide.

J. S. van Nest's curves for binary mixtures of mercury bromide with the iodide and chloride are shown in Fig. 25.

The transition point of the yellow to red form is lowered by admixture with mercuric bromide as illustrated in Fig. 26. The effect is represented by two curves between which lies a transition interval so that on one side only the α - or red crystals, and on the other side only the β - or yellow crystals, can exist. The fall of the curve is so very steep that the corresponding transition point for mercuric bromide, if it exists at all, must be below -83° . The yellow mixed crystals are also more stable at ordinary temp. than is the case with the yellow iodide alone, and this the more the larger the proportion of the bromide, as was observed by N. S. Kurnakoff and P. P. Ejler, and by G. Bruni and M. Padoa.

There is not so complete a series of mixed crystals between mercuric chloride and iodide as between the bromide and iodide. M. Padoa and C. Tibaldi obtained a V-shaped f.p. curve with a minimum at 145° with 48 per cent. of mercuric iodide. There is a gap in the series of mixed crystals with between 50 and 70 per cent. of mercuric chloride. The mixed crystals are red at ordinary temp., excepting only those with 1.3 molar per cent. of the iodide. The lowering of the transition temp. with the chloride is not so great as with the bromide. The mercuric halides are isotrimorphous in that they present three crystalline forms: (i) the rhombic form of the chloride—not isomorphous with that of the bromide; (ii) the rhombic form of the bromide; and (iii) the tetragonal form characteristic of the red iodide. The

FIG. 26.—Effect of Mercuric Bromide on the Transition Temperature of Mercuric Iodide.

bromide crystallizes with the chloride in the first form, and with the iodide in the second and third forms. A. Steger prepared mixed crystals of mercuric and silver iodides by melting and solidifying mixtures of the two salts. There is a gap in the series between 5 and 20 mols. per cent. of silver iodide. The mixed crystals with up to 5 mols. per cent. of silver iodide are of the rhombic mercuric iodide type; and those with upwards of 20 mols. per cent. are of the regular silver iodide type.

G. Wyrouboff wrongly supposed that the red and yellow iodides furnish each its own characteristic vapour, and that the vap. densities of the red iodide is greater than that of the yellow. It was thought that yellow mercuric iodide is formed by rapid condensation of the vapour, but that if the sublimation occurs at a low temp. red crystals may be obtained. D. Gernez has shown that in every case it is very probable that the yellow form is first deposited and that this subsequently becomes red. D. Gernez observed that even when the red salt is vaporized, yellow crystals are first formed by condensation from the vapour at temp. as low as 25°. M. L. Frankenheim noted that when a mixture of the red and yellow iodide is heated on a glass plate and allowed to condense on another plate held a short distance above, the sublimate is a mixture of both iodides. M. Berthelot, however, does not regard this as proving the existence of red iodide in the state of vapour because solid particles of the red iodide are projected mechanically from the lower plate to the upper, and convert the yellow iodide condensed in their immediate vicinity into the red. If either red or yellow mercuric iodide be vaporized in vacuo, at a relatively low temp., and a cooler solid is introduced, yellow crystals are deposited if the surface be thoroughly clean, but if the solid has been rubbed at one spot with a crystal of the red variety and a crystal of the yellow variety at another spot, D. Gernez showed that red crystals are deposited on the former, and yellow crystals on the latter.

When a mercuric salt is treated with potassium iodide, a pale yellow precipitate separates out, and this immediately becomes scarlet-red. According to R. Warington, under the microscope, the precipitate which is first formed with mercuric chloride appears to be composed of rhombic laminae, which are yellow by reflected light; these crystals gradually alter by the truncation of the edges and corners as if they were dissolving, and their dimensions are reduced until red square-based octahedrons are produced. R. Warington, and M. Berthelot also noted that if an alcoholic soln. of mercuric iodide be treated with water, or if a hot sat. alcoholic soln. be cooled, crystals of the yellow iodide are formed. According to L. Selmi, if an alcoholic soln. of mercuric iodide be poured into water, a yellow emulsion is formed from which yellow rhombic plates separate in a few hours; in agreement with the general behaviour of colloidal suspensions, M. L. Frankenheim and others noted that during the precipitation of salts by alcohol, an unstable liquid phase is first formed, and from this the salt then separates. The emulsion is quickly flocculated by the addition of acids or neutral salts. L. Selmi also found sulphuric acid acts like water; with nitric acid, yellow and red mercuric iodides are precipitated; and with hydrochloric or acetic acid, only the red iodide. H. Schiff, and A. Reynoso also made observations on the separation of mercuric iodide from alcoholic soln. It is probable that the yellow iodide is in all cases precipitated, and that the precipitate is more or less rapidly converted into the red iodide in the presence of different catalytic agents.

Analogous results have been reported with soln. of red and yellow mercuric iodides in methyl alcohol (W. D. Bancroft, and P. Rohland); in methylene iodide (J. W. Retgers); nitrobenzene, *m*- and *p*-nitrotoluene, *o*-nitronaphthalene (L. Mascarelli); alcohols, hydrocarbons, hydrocarbon halides, ethers, esters, aldehydes, ketones, organic acids and anhydrides, phenolamines, hydrazides, quinoline, pyridine (D. Gernez); allyl alcohol, amyl alcohol, acetone, phenol, benzene, toluene, naphthalene, ψ -cumene, propionitrile, isopropyl or isobutyl bromide, ethylidene chloride, ethyl and phenyl cyanides, benzoic acid, ethyl acetate, propionate, butyrate, *t*-butyrate, iodide, or bromide; propyl chloride, isobutyl bromide, methyl and

phenyl salicylate (J. H. Kastle and M. E. Clark). E. Beckmann and A. Stock report that the soln. of mercuric iodide in chloroform is violet; in benzene, red; and in ether, acetone, ethyl or methyl alcohol, brown; but the soln. are in general yellow and furnish yellow crystals when the hot sat. soln. is cooled; the pink colour of certain soln.—*e.g.* with isobutyl bromide or propyl chloride—is attributed by J. H. Kastle and M. E. Clark not to the presence of red mercuric iodide, but to the formation of unstable alkyl or similar iodides. Soln. of mercuric iodide in molten naphthalene or spermaceti are colourless, but become yellow if rapidly cooled, and red if slowly cooled below the transition temp. 127°. According to Lüppe Cramer, the presence of gelatine in the soln. favours the formation of the yellow iodide; and W. Ostwald stated that when precipitated from alcoholic soln. in the presence of a colloid, presumably gelatine, the yellow form of mercuric iodide can be preserved a long time. J. N. Friend also showed that in general protective colloids or organic emulsoids retard the velocities of chemical or physical reactions which involve a change of state in one or more of the components. For instance, in the precipitation of mercuric iodide from soln. of mercuric chloride and potassium iodide, the unstable yellow form first precipitated rapidly assumes the stable red form; but in the presence of one per cent. of gelatine, there is a momentary formation of colloidal iodide, and the canary-yellow precipitate which follows remains unchanged for half an hour. As indicated by W. Ostwald, R. Weber, H. Schiff, A. Reynoso, L. Selmi, etc., the change is accelerated by exposure to light.

L. Mascarelli found only one value for the solubility with both the red and yellow iodides at a definite temp., and that the solubility curves are continuous between 0° and 230° without the appearance of any break at the transition point of the red to the yellow iodide. Hence it is inferred that the yellow form alone exists in soln. at all temp. The yellow form separates in all cases, but below the transition temp. the yellow form persists for a length of time, depending on the distance of the temp. below the transition point. The yellow form of mercuric iodide which separates by cooling, say, a soln. of this salt in amyl alcohol from 150° to 118°, begins to develop spots of the red iodide in about 10 mins. W. W. Mather noted that potash-lye immediately turns the yellow iodide red. J. H. Kastle and J. V. Reed found the stability of the yellow iodide to vary greatly under different solvents. As a rule, the stability increases with the viscosity of this solvent, and is greater under vaseline than under any other solvent yet examined. In illustration, no change was observed after standing 1½ years under vaseline, the change began under glycerol in 1 to 5 weeks; and under amyl alcohol in 10 mins. W. Reinders also noted the slowness of the change from yellow to red when in contact with viscous liquids. This is in agreement with general experience that chemical and physical changes are slow in viscous solvents. J. H. Kastle and J. V. Reed also found that soln. of mercuric iodide in naphthalene sat. at 140° yield no solid when cooled to 100°; the supersaturated soln. is not usually affected by adding a crystal of the red iodide, but a crop of crystals of the yellow iodide are obtained when the soln. is seeded with a yellow crystal; other substances—*e.g.* powdered glass, gypsum, or dolomite—also lead to the separation of yellow crystals. Where a red crystal does cause a precipitation from yellow soln., yellow crystals are produced.

It almost seems as if the red iodide is insoluble in organic solvents and that the red iodide forms the yellow variety before it dissolves, as is evidenced by the slower rate of soln. of the red variety in naphthalene. W. Ostwald has stated that he considers there is no difference between the gaseous and liquid states of aggregation of different allotropic forms of a solid; the vapour of red phosphorus is identical with the vapour of yellow phosphorus; a soln. of rhombic sulphur in carbon disulphide is no different from a soln. of the monoclinic form; and different forms of many salts are obtained from under-cooled soln.—*e.g.* nickel sulphate—by introducing a fragment of the corresponding crystal. Consequently, physical isomerism occurs exclusively with solids, and disappears when the substance assumes another state of aggregation. So also with mercuric iodide, the same

soln. is obtained whether the red or yellow iodide be used at the start; and similarly also with the vapour. This idea can be symbolized: $\text{HgI}_{2\text{gas}} \rightleftharpoons \text{HgI}_{2\text{liquid}} \rightleftharpoons \text{HgI}_{2\text{yellow solid}} \rightleftharpoons \text{HgI}_{2\text{red solid}}$.

J. H. Kastle and M. E. Clark say that the separation of the yellow iodide from soln. appears to indicate that the transition temp. is lowered by the solvent; but the precipitation of the less stable yellow form of mercuric iodide from soln., or from supersaturated soln., or its formation by double decomposition, is usually cited as an illustration of W. Ostwald's generalization that *when a substance leaves any state and passes into another more stable one, the one actually produced is not the most stable one under the existing conditions, but the one which can be reached with the minimum loss of free energy*. For example, of the two possible forms of mercuric iodide the yellow less stable form is the first to appear during sudden precipitation. The theory of the allotropic states of mercuric iodide has been discussed by A. Smits, G. Tammann, M. Hasselblatt, etc.

The reported values⁵ for the **specific gravity** of red mercuric iodide vary from H. Schiff's 5.91 to J. S. van Nest's 6.2939 (20°); the latter gave 6.282 (20°) for the yellow iodide. F. W. Clarke's value for the mean of seven determinations is 6.231. According to G. F. Rodwell, the sp. gr. of the red iodide at 0° is 6.2972; and at 126°, 6.276; the sp. gr. of the red iodide at 126° is 6.225; at the m.p. 200°, the sp. gr. of the solid is 6.179, and of the liquid, 5.286. K. Beck gives 5.34 for the sp. gr. of the liquid at 258°; and E. B. R. Prideaux gave for the sp. gr. of the liquid at a temp. θ between 255° and 355°, $5.238 - 0.00322(\theta - 255)$. W. Biltz gave 72.2 for the mol. vol. of yellow mercuric iodide, assuming the sp. gr. is 6.297 (0°). A. Reis and L. Zimmermann gave 2.0 for the **hardness** on Mohs' scale. The **coefficient of cubical expansion** from 0° to the transition point 126° was found by G. F. Rodwell to be 0.0000344706 per degree for the red iodide; and for the yellow iodide from 126° to 200°, 0.0001002953 per degree. P. W. Bridgman gives the

FIG. 27.—Relation between the Volume and Temperature of Mercuric Iodide.
—G. F. Rodwell.

change in the coeff. of thermal expansion with press. as -0.000038 at a press. of one kilogram per sq. cm.; -0.000036 at 2000 kgrms. per sq. cm.; $+0.000020$ at 6000, $+0.000023$ at 8000, and $+0.000021$ at 10,000 kgrms. per sq. cm. The changes in volume which occur between 0° and 200° are illustrated in Fig. 27. According to W. Reinders, the change of volume at the transition temp. is 0.00135 c.c. per gram, and to P. W. Bridgman, 0.00342 per gram as indicated in Fig. 27.

The change from yellow to red, during

the cooling of mercuric iodide, is accompanied by distinct crackling sounds.

H. V. Regnault⁶ found the **specific heat** of mercuric iodide between 18° and 99° to be 0.0420; W. Schwarz, between 22° and 131°, 0.0413; J. Guinchant found 0.0406 between 0° and 100°, and for the fused salt, 0.0554; and H. Barschall found between -72.5° and -183.3° , 0.0376; and between -78.2° and -183.3° , 0.0370. At atm. press., the yellow iodide has the larger sp. ht. J. Guinchant gives the difference as 0.0040 cal., but, according to P. W. Bridgman, as the press. increases the difference becomes less. E. Goldstein found the **molecular heat** to be 6.4, and at low temp. down to -183.3° , 17.0. When the iodide is heated above the transition temp. the yellow colour gradually darkens, and just before the m.p. is attained the solid becomes a deep reddish-brown. According to G. F. Rodwell, the **melting point** of the solid is 200°, and, according to A. Oppenheim, 238°, but more recent measurements show that these numbers are much too low—R. Warington, and T. Carnelley and W. C. Williams gave 238° to 238.1° ; E. Beckman, 250° ; H. Köhler, 253° to 254° ; C. Sandonnini, and M. Padoa and C. Tibaldi, 254° ; W. Reinders, 255.4° ; and A. Smits, 255.5° . J. S. van Nest gave 245° for the m.p.

of the yellow iodide, and 243° for the red iodide. When heated slowly, the yellow colour gradually changes to orange, without a change in the crystalline form, as the temp. approaches 200° , and the molten liquid is dark red. By extrapolation, F. M. G. Johnson estimated the **boiling point** to be 351° . The colour of molten mercury iodide is very like that of bromine. A portion of A. Smits' equilibrium diagram is shown in Fig. 28. The colour of red mercuric iodide persists from S_3 to S_2 , because the mols. of the red iodide predominate; at the transition point, S_2 to S_1 , there is a change, so that the red mols. preponderate; the change to orange is attended by a gradual increase in the proportion of red mols., and at the m.p., SS_0 , the red mols. again preponderate and form a red liquid. The m.p. of the yellow iodide is represented diagrammatically at A.

K. Beck found the **viscosity** of molten mercuric iodide at 258° to be 3.963 (water at 25° unity). According to P. W. Bridgman, the coefficient of **compressibility** is 0.00000033 c.c. per gram per kilogram per sq. cm. N. S. Kurnakoff and S. F. Schemtschuschny give the **flow pressure** as 67.8 kgrms. per sq. mm. According to E. Beckmann, the **latent heat of fusion** per gram is 12.4 cal.; J. Guinchant gave 9.79 Cals. at 250° . According to E. Beckmann, the **molecular weight** computed from the lowering of the f.p. of iodine is 463 when the value calculated for HgI_2 is 454. J. Timmermanns obtained higher values indicating a partial association of the mol., but E. Beckmann ascribes this to the use of too high a value for the freezing constant of iodine. F. Garelli and V. Bassani find mercuric iodide has a normal mol. wt. when determined by its action on the f.p. of methylene iodide. W. Herz and M. Knoch found that the raising of the b.p. of alcohol by mercuric iodide corresponds with the normal mol. HgI_2 . H. Steiner and J. Schröder found that in soln. of methyl acetate the b.p. method corresponds with a mol. wt. 335 to 404.2—in approximate agreement with a 10 per cent. ionization of the salt. M. Hamers found a mol. wt. of 430.5 in ethyl acetate soln.; A. Werner, 462 in methyl sulphide; 457 in ethyl sulphide; 474 in benzonitrile; and 408 in pyridine; J. Schröder found a mol. wt. of 436 in pyridine soln.; and P. Walden and M. Centnerszwer say that in very dil. pyridine soln. the mol. wt. is normal, and that it decreases slowly with increasing conc.

According to C. Zenghelis, the vaporization of mercuric iodide can be detected at ordinary temp.; V. Borelli also detected it at 80° . H. Saha and K. N. Choudhuri found 2.4359 grms. lost 0.0376 grm. in 12 hrs. at 100° ; O. Sule found a loss of 5.4 per cent. when the finely powdered salt is heated 6 hrs. at 101.5° , and H. Arctowsky found that when heated 5 hrs. at 80° , the salt lost 0.06 per cent.; at 103° , 0.70 per cent.; and at 130° , 4.2 per cent. The **vapour pressure**, p , from 100° to 330° has been determined by E. Wiedemann, K. Stelzner, and G. Niederschulte, and their values below 177° , and F. M. G. Johnson's values above this temp. are:

Temp. . . .	100°	150°	177°	203°	253°	266°	301°	318°	341°
p	0.023	0.79	3.0	10.0	73.0	108	260	390	624

No change in the slope of the curve was observed by F. M. G. Johnson at the m.p., although W. Reinders noted such a change. Vap. press. measurements have also been made by A. Ditte, and by E. B. R. Prideaux. T. Carnelley and W. C. Williams' value for the **boiling point** lies between 339° and 359° ; W. Hittorf's value is 358° . F. M. G. Johnson obtained 351° at 760 mm. by extrapolation of the vap. press. curve. L. Rotinjan and W. Suchodsky found the **critical temperature** to be 1072° , a result in agreement with the value 1077° calculated from T. E. Thorpe and

FIG. 28.—Diagrammatic Representation of the Binary System α - HgI_2 and β - HgI_2 .

A. W. Rucker's formula. C. M. Guldberg's ratio $T_b/T_c=0.584$, where T_b and T_c respectively denote the b.p. and critical temp. in absolute degrees. H. Rassow gave 797° for the critical temp. of mercuric iodide. M. Prud'homme, and E. van Aubel studied the relation between the critical temp., the b.p., and the m.p. According to F. M. G. Johnson, the **heat of vaporization** is 15.84 cals., and, according to E. B. R. Prideaux, 14.7 cals.; and the corresponding values of **Trouton's constant** Q/T are 25.47 and 23.5 respectively. According to **W. Ramsay's rule**, b.p. at T_1 and 750 mm. and at T_2 and 450 mm., the ratio T_1/T_2 is 1.040 for mercuric chloride, 1.043 for the bromide, and 1.042 for the iodide. The molten salt heated in a large glass balloon furnishes a colourless vapour which becomes coloured as the vapour dissociates. H. St. C. Deville noted that the vapour is violet near the walls of the vessel, and colourless nearer the middle, and L. Troost found that the dissociation increases as the temp. rises, so that at 665° , about one-fifth of the vapour is dissociated. H. Debray noted that gold-leaf is whitened and powdered by the dissociating vapour of mercuric iodide. E. Mitscherlich found the **vapour density** to be 15.6 to 16.2 ; and L. Troost, 15.89 at 17.6° , and 14.9 at 15.4° —the theoretical value is 15.712 .

According to J. Thomsen,⁷ the **heat of formation** of mercuric iodide from its elements is $(\text{Hg}, \text{I}_2)=34.31$ Cals.; $(2\text{HgI}, \text{I}_2)=20.18$ Cals.; $(\text{HgCl}_{2\text{aq.}}, 2\text{KI}_{\text{aq.}})=26.75$ Cals.; $(\text{HgO}, 2\text{HI}_{\text{gas}})=84.07$ Cals. M. Berthelot found $\text{HgO}+2\text{HI}_{\text{soln.}}=\text{HgI}_{2\text{red}}+46.4$ Cals. and $=\text{HgI}_{2\text{yellow}}+43.4$ Cals. R. Varet gives $\text{HgI}_{\text{liquid}}+\text{I}_{2\text{solid}}=\text{HgI}_{2\text{red}}+25.2$ Cals., and $=\text{HgI}_{2\text{yellow}}+22.2$ Cals.; $\text{HgI}_{\text{liquid}}+\text{I}_{2\text{gas}}=\text{HgI}_{2\text{red}}+38.8$ Cals., and $=\text{HgI}_{2\text{yellow}}+35.8$ Cals. Consequently, as noted by R. Weber, and G. F. Rodwell, heat is absorbed when the red iodide changes to yellow, and evolved when the yellow iodide changes to red. R. Weber found that a thermometer, dipping in the crystals during the change from the yellow to the red iodide, rose by 3° or 3.5° . According to M. Berthelot, the heat of transformation, $\text{HgI}_{2\text{yellow}}=\text{HgI}_{2\text{red}}+3.0$ Cals.; W. Schwarz gives 1.1516 Cals.; J. Guinchant, 1.53 Cals. as 130° ; and P. W. Bridgman, 1.2 Cals. as indicated in Table X. M. S. Sherrill gives the **free energy** of formation of mercuric iodide from its ions as 48.6 Cals.

The red crystals of mercuric iodide have a strong negative double refraction; according to E. Taubert,⁸ the ordinary ray is blood-red, the extraordinary ray, orange-red. G. D. Liveing found soln. of mercuric iodide in potassium iodide have a greater index of refraction than flint glass, or carbon disulphide; for soln. of sp. gr. 2.77 , at 18° , he found the **index of refraction** for the *A*-line to be 1.628 ; *B*-line, 1.637 ; *C*-line, 1.641 ; *D*-line, 1.654 ; *E*-line, 1.673 ; and for the *F*-line, 1.693 . A. Lesure says that the soln. are almost opaque to ultra-violet rays. J. A. Wilkinson found mercuric iodide gives a yellow fluorescence. E. L. Nichols and B. W. Snow measured the reflecting power, i , of mercuric iodide for rays of different wave-length, λ , at different temp.:

λ	.	.	.	0.7530	0.6689	0.6080	0.5570	0.5185	0.4920	0.4500
i at 25°	.	.	.	0.895	0.771	0.330	0.050	0.053	0.054	0.055
i at 122°	.	.	.	0.846	0.744	0.066	0.046	—	0.044	0.032

According to H. von Jüptner, the red iodide prepared in the wet way appears to be colourless in the light from a sodium flame. A. L. Hughes found the **photo-electric effect** of mercuric iodide to be rather less than that of mercurous iodide. O. Schönrock measured the **electromagnetic rotation** of alcohol and pyridine soln. of mercuric iodide.

B. O. Peirce⁹ found the **emission spectrum** of mercuric iodide gave continuous bands with the mid-point about 4430 . A. C. Jones extended the results into the ultra-violet, and A. K. Chapman found a wide emission band shading off to the violet and red, and he claimed that there is a definite relation between the emission and absorption spectra, so that the vibrating system responsible for the emission is responsible for absorption in soln. C. Sheard and C. S. Morris found

that with mercuric iodide there are continuous regions or bands between 6072 and 5845; 5605 and 5535; 5195 and 5132; 4828 and 4788; 4506 and 4470; and 4450 and 4375.

According to S. Meyer,¹⁰ the **magnetic susceptibility** of mercuric iodide is -0.26×10^{-6} units of mass. W. Beetz measured the **electrical conductivity** of solid mercuric iodide at about 110° ; and A. Gockel found that the solid is quite a good conductor between 229° and its m.p. 250° . W. Hampe did not find the yellow solid a conductor. M. Faraday, and J. W. Clark said that the molten iodide conducts electrolytically. W. Beetz added that the molten liquid about the anode is blackened by the separation of iodine, but no mercury appears at the cathode, and accordingly W. Hampe concluded (i) that the mercuric iodide decomposes into iodine and mercury, (ii) the mercury unites with mercuric iodide to form mercurous iodide, and (iii) the mercurous iodide dissolves in the molten electrolyte. J. W. Clark also noted the formation of mercurous iodide during the electrolysis of molten mercuric iodide between graphite electrodes. F. Kämpf found that for low current densities, red mercuric iodide is ten times better conducting in light than in darkness.

F. Kohlrausch and F. Rose have studied the electrical conductivity of aq. soln. of mercuric iodide; and C. Fritsch found the conductivity to be augmented by the addition of one per cent. of potassium iodide. The ionic concentration, in soln. of mercuric iodide: $\text{HgI}_2 = \text{HgI}^+ + \text{I}^-$ is 10^{-7} , and E. Abel emphasizes how very small is the degree of ionization of the salt. H. N. Morse gives for the ionization constants $[\text{Hg}^{++}][\text{I}^-] = 0.4 \times 10^{-13}[\text{HgI}^+]$; $[\text{HgI}^+][\text{I}^-] = 2.5 \times 10^{-12}[\text{HgI}_2]$; $[\text{Hg}^{++}][\text{I}^-]^2 = 10^{-25}[\text{HgI}_2]$; and $[\text{Hg}^{++}][\text{HgI}_2] = 0.016[\text{HgI}^+]^2$. M. S. Sherrill gives for the formation of complexes $[\text{Hg}^{++}][\text{I}^-]^4 = 1.9 \times 10^{-30}[\text{HgI}_4'']_5$ and $[\text{HgI}_2][\text{I}^-]^2 = 7.3 \times 10^{-5}[\text{HgI}_4'']$; he also estimates that in a sat. soln. of mercuric iodide the concentrations of the different kinds of mols and ions are HgI_2 , 1.3×10^{-4} ; HgI^+ and I^- , 1.8×10^{-8} ; Hg^{++} , 10^{-13} ; HgI_4'' , 2×10^{-14} . The **transport numbers** have been studied by H. N. Morse, and E. Rieger.

The electrical conductivity of soln. of mercuric iodide in liquid ammonia have been measured by H. P. Cady; in alcohol and in ether by W. Hampe, and by C. Cattaneo; in liquid methylamine by H. D. Gibbs, and by F. F. Fitzgerald; in pyridine, by A. Sachanoff, and A. T. Lincoln; in allyl mustard oil, by J. H. Mathews; in methyl acetate, by H. Steiner; and in acetic anhydride, acetone, epichlorhydrin, methyl alcohol, ethyl acetate, acetyl chloride, salicylaldehyde, aniline, dimethyl sulphate, and benzonitrile by L. I. Shaw.

M. Saladin¹¹ found the **solubility** of mercuric iodide in water to be very small, and H. Arctowsky noted that the solubility increased considerably with a rise of temp. The aq. soln. are more or less hydrolyzed, and H. Arctowsky noted the formation of a mercuric oxyiodide at 170° . The brownish six-sided rhombohedral crystals obtained by M. Saladin by the spontaneous evaporation of the aq. soln. are probably an oxyiodide. E. Bourgoin says that at 17.5° a litre of water dissolves 0.0403 grm. of the iodide; and at 22° , 0.0536 grm. P. Rohland obtained a similar result. H. N. Morse found a solubility of 0.06 grm. per litre at 25° . F. Kohlrausch and F. Rose reported much lower values, namely, 0.002 milligram eq. or 0.0004 grm. per litre at 18° ; and later F. Kohlrausch gave 0.0002 to 0.0004 mgrm.; M. S. Sherrill, R. Aegg, and G. Bodländer have also made estimates of the solubility of mercuric iodide in water. The discordant data correspond with A. C. Dunningham's statement that the solubility of mercuric iodide in water is too small to estimate accurately. As previously indicated, both the red and yellow modifications form identically the same soln.

The solubility of mercuric iodide in *methyl alcohol* between 15° and 20° is given by P. Rohland as 3.24 grms. of salt per 100 grms. of alcohol and the sp. gr. of the soln. is 0.799. C. A. L. de Bruyn gives 3.16 grms. at 19.5° ; and O. Sulc, 6.512 grms. at 66° , the b.p. W. Herz and G. Anders found at 25° 10 c.c. of methyl alcohol dissolve 0.259 grm. of mercuric iodide, and that the solubility decreases as the

proportion of water increases, being 0.0445 grm. with 78.05 per cent. alcohol; 0.0158 grm. with 64 per cent. alcohol; and 0.0044 grm. with 47.06 per cent. alcohol. P. Rohland found 100 grms. of *ethyl alcohol* at 15° to 20° dissolve 1.42 grms. of mercuric iodide (sp. gr. of soln. 0.810); E. Bourgoïn, 1.48 grms. at 18°; C. A. L. de Bruyn, 2.09 grms. at 19.5°; W. Herz and M. Knoch, 2.19 grms. at 25° (sp. gr. of soln. 0.803); and O. Sulc, 4.325 grms. at 78°, the b.p. O. Schönrock measured the sp. gr. of alcoholic soln. The solubility is diminished with increasing proportions of water, thus, at 25°, W. Herz and M. Knoch found 100 c.c. of a soln. of 95.82 per cent. alcohol have 1.162 grms. of mercuric iodide; 86.74 per cent. alcohol, 0.623 grm.; and 67.63 per cent. alcohol, 0.204 grm. The sp. gr. of the three last-named soln. are 0.80950, 0.82996, and 0.87214 respectively. W. Herz and F. Kuhn have measured the solubility of mercuric iodide in mixtures of methyl and ethyl alcohols. P. Rohland found 100 grms. of *propyl alcohol* dissolve 0.826 grm. of mercuric iodide between 15° and 20°, and the soln. has a sp. gr. 0.816. W. Herz and F. Kuhn have measured the solubility of mercuric iodide in mixtures of propyl alcohol with ethyl and with methyl alcohols. S. von Laszcynsky found that 100 grms. of *amyl alcohol* at 13° dissolve 0.66 grm. of mercuric iodide; at 71°, 3.66 grms.; at 100°, 5.30 grms.; and at 133.5°, 9.57 grms. O. Sulc found 100 grms. of *isopropyl alcohol* at its b.p., 81°, dissolve 2.266 grms. of mercuric iodide; and *isobutyl alcohol* likewise at its b.p., 105°–107°, 2.433 grms. J. H. Kastle and M. E. Clark say that mercuric iodide is more soluble in *allyl alcohol* than in ethyl alcohol. N. A. Orloff and M. Adams have studied the reactions of mercuric iodide in alcoholic soln.

M. Saladin noted in 1831 the low solubility of mercuric iodide in *ether*; according to S. von Laszcynsky, 100 grms. of ether dissolve 0.62 grm. of the iodide at 0°, 0.97 grm. at 36°, and, according to O. Sulc, 0.47 grm. at 35°, the b.p. of ether. S. G. Liversedge, and M. François used the fact for extracting mercuric iodide from certain mixtures in analytical work. S. von Laszcynsky found the solubility of mercuric iodide in 100 grms. of *acetone* to be 2.83 grms. at –1°; 3.36 grms. at 18°; 4.73 grms. at 40°; and 6.07 grms. at 58°. W. H. Krug and K. P. McElroy give 2.09 grms. at 25°, and O. Sulc gives 3.249 grms. at 56°, the b.p. W. Reinders gives a solubility of 1.95 per cent. for the red and 3.00 per cent. for the yellow iodide at 25°, but it is probable that equilibrium was not attained with the red salt. D. Gernez and L. Levi Bianchini have studied the reactions of mercuric iodide in acetone soln. D. Gernez found mercuric iodide to be soluble in *acetaldehyde*, W. Reinders in *benzaldehyde*, and L. I. Shaw in *salicylaldehyde*. According to O. Sulc, 100 grms. of *chloroform* dissolve 0.040 grm. of the iodide at 18°–20°, and 0.163 grm. at 61°, the b.p.; *bromoform*, 0.486 grm. at 18°–20°; *carbon tetrachloride*, 0.006 grm. at 18°–20°, and 0.094 at 75°, the b.p.; *ethyl bromide*, 0.643 grm. at 18°–20°, and 0.773 grm. at 38°, the b.p.; *ethylene dibromide*, 0.748 grm. at 18°–20°; H. Gautier and G. Charpy give 0.553 grm. at 15°. O. Sulc further found that 100 grms. of *ethyl iodide* dissolve 2.041 grms. of mercuric iodide at 18°–20°; *ethylene dichloride*, 1.200 grms. at 8.55°, the b.p.; *isobutyl chloride*, 0.328 grm. at 69°. J. H. Kastle and M. E. Clark found mercuric iodide to be soluble in *ethyl bromide*, *propyl bromide*, and *butyl bromide*. W. Reinders also found it to be soluble in *amyl bromide*, *amyl iodide*, *benzyl iodide*, and *naphthyl bromide*. O. Sulc found 100 grms. of *methyl formate* dissolve 1.166 grms. at 36°–38°; *ethyl formate*, 2.150 grms. at 52°–55°; *methyl acetate*, 2.500 grms. at 56°–59°; J. Schröder and H. Steiner also found 2.3 grms. were dissolved at the b.p. of this solvent, and F. Bezold, 1.1 grms. at 18°. According to E. Alexander, mercuric iodide is slightly soluble in *ethyl acetate*; M. Hamers found 100 grms. of the anhydrous solvent at 18° dissolve 1.470 grms. or 0.0033 mols of the iodide, and that the solubility increases with rise of temp. W. Herz and G. Anders measured the solubility of mercuric iodide in mixtures of *ethyl acetate* and water. J. H. Kastle and M. E. Clark found mercuric iodide to be very soluble in *ethyl propionate*, *ethyl butyrate*, *ethyl isobutyrate*, *ethyl salicylate*, and *phenyl salicylate*. W. Reinders found mercuric iodide to be soluble in *amyl acetate*. S. von Laszcynsky found 100 grms. of ethyl acetate dissolved 1.49 grms. of mercuric iodide at –20°; 1.56 grms. at 17.5°; 1.64 grms. at 21°; 2.53 grms. at 40°; 3.19 grms. at 55°; 4.31 grms. at 76°; and O. Sulc says 4.20 grms. at the b.p. 74°–78°. W. Reinders says that *diethyl oxalate* at its b.p. dissolves 12.5 per cent. of mercuric iodide, and 2.5 per cent. at 100°. F. Bezold and M. Hamers have studied the chemical reactions of mercuric iodide in soln. of ethyl acetate. O. Sulc found 100 grms. of *acetal* dissolve 2.000 grms. of mercuric iodide at 105°; *epichlorhydrin*, 6.113 grms. at 117°; and *hexane*, 0.072 grm. at 67°. J. W. Retgers found 100 grms. of *methylene iodide* dissolved 2.5 grms. of the iodide at 15°, 16.6 grms. at 100°, and 58.0 grms. at 180°. S. von Laszcynsky also gives for 100 grms. of *benzene*, 0.22 grm. at 15°; 0.88 grm.

at 60°; 0.95 grm. at 65°; 1.24 grms. at 84°; O. Sulc gives 0.825 grm. at the b.p., 80°; and H. Gautier and G. Charpy, 0.217 grm. at 15°. C. Melm and A. P. N. Franchimont also studied the solubility of mercuric iodide in *benzene*, and M. S. Sherrill, the partition coeff. of this salt between water and benzene. J. H. Kastle and M. E. Clark say mercuric iodide is more soluble in *toluene* than in alcohol. W. Reinders found mercuric iodide to be soluble in *acetic acid*, M. Rosenfeld in *acetic anhydride*, and G. C. Wittstein in soln. of *ammonium succinate*. A. Werner says that mercuric iodide is sparingly soluble in *methyl sulphide* and *ethyl sulphide*, and that there is some decomposition, gas is evolved, and addition products are formed. J. H. Mathews also says mercuric iodide is soluble in *allyl mustard oil*. A. Werner found ethyl sulphide forms addition products. F. F. Fitzgerald, and H. D. Gibbs said that mercuric iodide is very soluble in *methylamine*; H. Vohl, in *aniline*. According to M. François, mercuric iodide in aniline soln. is reduced to mercury when the soln. contains more than 26 grms. of mercuric iodide to 100 grms. of aniline. J. H. Kastle and M. E. Clark said that mercuric iodide is soluble in *naphthalene*, in *ψ -cumene*, *ethyl cyanide*, *phenyl cyanide*; L. Mascarelli, in *nitrobenzene*, *nitrotoluene*, and *nitronaphthalene*; and A. Werner, in *benzonitrile* and other aromatic nitriles. A. Naumann said that at 18°, 100 grms. of benzonitrile dissolve 0.98 grm. of mercuric iodide, and that the solubility is much greater if potassium iodide be present. W. Eidmann found mercuric iodide to be soluble in *methylal*. M. François found mercuric iodide to be very soluble in *phenol*, for 100 grms. of boiling phenol dissolve 110 grms. of mercuric iodide; C. Méhu gave 2.0 grms. per 100 grms. of solvent at 100°. J. Schröder and A. Naumann also found mercuric iodide to be soluble in *pyridine*; W. Reinders in *toluidine*; and D. Gernez in *quinoline*. O. Schönrock measured the sp. gr. of pyridine soln. J. Schröder has studied the chemical reactions of mercuric iodide in soln. of pyridine. A. Werner found the *piperidine* reduces mercuric iodide to the metal, the reaction is instantaneous at 100°. C. Méhu found that 100 grms. of *bitter almond oil* dissolved 0.5 grm. of mercuric iodide at 25°, and 1.3 grms. at 100°; *castor oil*, 4.0 grms. at 25°, 20.0 grms. at 100°; *nut oil*, 1.3 grms. at 100°; *vaseline*, 0.025 grm. at 25°, 0.20 grm. at 100°; *poppy oil*, 1.0 grm. at 25°; and *olive oil*, 0.4 grm. at 25°. W. Reinders also noted the solubility of mercuric iodide in *turpentine* and *petroleum*. M. C. Lea found mercuric iodide dissolves readily in hot *glycerol*, forming a colourless soln., and T. Fairley said that 100 parts of glycerol dissolve 0.294 part of the salt.

According to P. Walden,¹² mercuric iodide is soluble in *sulphur chloride*, S_2Cl_2 , forming a reddish-brown soln.; in *thionyl chloride*, $SOCl_2$, forming a reddish-yellow soln.; in *sulphuryl chloride*, SO_2Cl_2 , forming a yellow soln.; in *phosphoryl chloride*, $POCl_3$, forming a colourless soln.; in *phosphorus tribromide*, PBr_3 , forming a yellowish coloured soln.; and in *arsenic trichloride*, $AsCl_3$, and in *arsenic tribromide*, $AsBr_3$, forming colourless soln. E. H. Büchner finds mercuric chloride to be insoluble in liquid *carbon dioxide*. According to P. Walden and M. Centnerszwer, mercuric iodide is soluble in liquid *sulphur dioxide*. The sat. soln. at the critical temp., 158.2°, contains 0.7 per cent. of mercuric iodide, and the critical temp. of the soln. increases with increasing conc. P. Niggli said that liquid sulphur dioxide in a sealed tube at 254° contains 6.2 per cent. of mercuric iodide in soln. The presence of potassium or rubidium iodide, or of mercuric bromide augments the solubility of mercuric iodide. C. E. Linebarger, H. Arctowsky, and H. Gautier and G. Charpy have measured the solubility of mercuric iodide in *carbon disulphide*. The percentage solubility, *S*, is

	-116°	-86.5°	-10°	0°	5°	10°	15°	20°	25°	30°
<i>S</i>	0.017	0.024	0.107	0.173	0.207	0.239	0.271	0.320	0.382	0.445

Mercuric iodide is **photosensitive** for R. Hunt,¹³ and Lüppo Cramer showed that a film of this salt becomes brown on exposure to light; and J. W. Slater found that blue light is particularly favourable in producing the change. O. Sulc observed that when a soln. of mercuric iodide in alcohol, chloroform, or ethyl bromide is exposed to light, free iodine and mercurous iodide are formed. The photosensitiveness of mercuric iodide in photographic emulsions has been studied by Lüppo Cramer, F. Kropf, A. P. H. Trivelli and S. E. Sheppard, etc. The results show that the emulsions are not so sensitive photochemically as those of the silver halides; that the red emulsion is more sensitive than the yellow emulsion; and that the yellow emulsion made at 80° is not so sensitive as the others. While mercuric and silver iodides are fairly sensitive, the double salt is only slightly so.

M. Berthelot¹⁴ found that purified mercuric iodide is not decomposed if exposed

dry or moist in a sealed tube for a month to **sunlight**, and the decomposition often observed with pharmaceutical preparations is due to the reducing action of organic compounds. M. C. Lea noted that mercuric iodide is darkened and even blackened by the application of a high *pressure* without the liberation of iodine, for none could be extracted by alcohol. F. C. Phillips sublimed mercuric iodide in a stream of **hydrogen** without reduction; and H. Schulze calcined it in **oxygen** without decomposition. M. Kohn and A. Ostersetzer found that mercuric halides are reduced by **hydrogen peroxide** in alkaline soln., or by **sodium peroxide** with the liberation of mercury, and the reaction has been applied in quantitative analysis.

C. F. Rammelsberg obtained what he regarded as **tetramercuric trioxiodide**, $\text{HgI}_2 \cdot 3\text{HgO}$, by melting together mol. proportions of the two components; and he, as well as T. Weyl, obtained a similar product by the action of a dil. soln. of potassium hydroxide on mercuric oxide. A. Oppenheim also obtained a similar product by the crystallization of allylmercuric iodide from acetone. The yellow product is decomposed by drying at 100° , and when exposed to the action of dry ammonia. P. Yvon also obtained a pale yellow sublimate—approximately $7\text{HgI}_2 \cdot 6\text{HgO}$ —by rapidly heating mercurous iodide. The mixture decomposes on exposure to light, and turns red. H. Moissan noted that **fluorine** attacks mercuric iodide in the cold, the reaction is accompanied by *une flamme très vive*, and the formation of a yellow compound—mercuric fluoride or iodo-fluoride. Molten **ammonium fluoride** was found by C. Poulenc not to attack mercuric iodide. E. Filhol noted that if **chlorine** be passed through water in which mercuric iodide is suspended, mercuric chloride and iodine trichloride are formed. According to M. Berthelot, the displacement of iodine by chlorine develops 14.3 Cals. with red mercuric iodide, and 17.3 Cals. with the yellow salt. P. Hautefeuille found that mercuric iodide is not decomposed when heated in a stream of **hydrogen chloride**; J. J. Colin, P. F. G. Boullay, H. Saha and K. N. Choudhuri noted that the salt is soluble in **hydriodic acid**, and also in **hydrochloric acid**, and, according to H. Köhler, conc. hydrochloric acid is one of the best agents for crystallizing mercuric iodide since the hot acid dissolves a considerable amount of the salt without decomposition. C. F. Rammelsberg found that mercuric iodide dissolves in a soln. of **bleaching powder**, and when the soln. is heated a gelatinous mass of basic calcium periodate is deposited and mercuric chloride remains in soln. J. W. Clark noted that a soln. of mercuric iodide dissolves mercurous iodide and iodine. J. H. Kastle and M. E. Clark found that **cyanogen iodide**, CyI , decomposes mercuric iodide in suspension in water, forming mercuric cyanide and iodine.

J. Timmermanns found that soln. of mercuric iodide in iodine give high values for the mol. wt. F. Olivari said that this is not to be attributed to the formation of **mercuric polyiodides** since the f.p. curve of mixtures of mercuric iodide and iodine shows no signs of their formation. The curve has a eutectic at 101.4° with 12.5 molecular per cent. of mercuric iodide. S. Schlesinger obtained a white powder by the action of hot fuming nitric acid on mercuric iodide; this product, once thought to be *mercuric periodide*, HgI_3 , was shown by S. M. Jörgensen to be mercuric iodate. R. Hunt also obtained a purplish-brown product—with 27.9 per cent. of mercury and 72.1 per cent. of iodine—very nearly corresponding with HgI_4 , by the action of a soln. of potassium iodide sat. with iodine upon an aq. soln. of mercuric chloride. There is nothing to show that the product is a homogeneous or chemical individual. S. M. Jörgensen treated a hot (50°) alcoholic soln. of potassium triiodide with an excess of a cold aq. soln. of mercuric chloride, and obtained a brown crystalline precipitate which was rapidly washed with cold water. It could not be dried without decomposition. The product is thought to be a mixture of **mercuric hexaiodide**, HgI_6 , with some red and yellow mercuric iodides. The brown crystals belong to the rhombic system, and in form resemble yellow mercuric iodide; they are slowly decomposed by cold water; they gradually lose iodine on exposure to air; they are reduced by zinc and cold water, forming zinc iodide and zinc amalgam; and they are decomposed by alcohol, forming red mercuric iodide. W. Herz and

W. Paul measured the solubility of iodine in mercuric chloride soln., and partition experiments with carbon tetrachloride indicate the existence of **mercuric dibromiodide**, HgBr_2I_2 , and of **mercuric dichloriodide**, HgCl_2I_2 .

Mercuric iodide is not attacked by **sulphuric acid** in the cold, but when heated, the salt is decomposed; A. Ditte did not obtain salts analogous with $\text{HgSO}_4 \cdot 2\text{HBr}$ and $\text{HgSO}_4 \cdot 2\text{HCl}$ as is the case when sulphuric acid reacts with the corresponding mercuric halides. K. Barth found that although mercuric iodide dissolves in soln. of the **alkali sulphites**, he could not obtain double salts analogous with those obtained with mercuric chloride or bromide. F. Field and E. Meusel found mercuric iodide dissolves in a soln. of **sodium thiosulphate**, and when the colourless liquid is heated, it deposits red mercuric sulphide; J. M. Eder and G. Ulm say that two mols are required for dissolving one of mercuric iodide, and C. F. Rammelsberg supposes that a double salt is formed.

The solvent action of liquid **ammonia**, and the formation of ammonia compounds of mercuric iodide are discussed in a special section. K. A. Hofmann and E. C. Marburg prepared **mercuric hydrazine-iodide**, $\text{HgI}_2 \cdot \text{N}_2\text{H}_4$, by adding an excess of hydrazine hydrate to an alcoholic soln. of mercuric iodide. The resulting yellow needle-like crystals are more stable than the corresponding bromide or chloride. They are decomposed by exposure to light, and by treatment with water. S. Schlesinger found mercuric iodide to be soluble in **nitric acid**; according to K. Kraut, when nitric acid of sp. gr. 1.5 is boiled with mercuric iodide, mercuric iodate, $\text{Hg}(\text{IO}_3)_2$, is formed, and a similar result is obtained with an acid of sp. gr. 1.4, but a small quantity of mercuric nitrate then passes into soln.; with an acid of sp. gr. 1.3, white micaceous plates of **mercuric nitratiodide**, $\text{HgI}_2 \cdot \text{Hg}(\text{NO}_3)_2$, separate out on cooling; and finally, with an acid of sp. gr. 1.2, red crystals of unchanged mercuric iodide accompanied by white scales of the nitrate-iodide separate out on cooling. According to F. Venturoli, alcoholic soln. of **phosphorus** and mercuric iodide give a compound, **mercuric phosphiodide**, Hg_2PI_3 , or $\text{PI}(\text{HgI})_2$, presumably: $8\text{HgI}_2 + 6\text{P} = 2\text{PI}(\text{HgI})_2 + \text{P}_2\text{I}_4$; and when heated, $\text{PI}(\text{HgI})_2 = \text{HgI}_2 + \text{HgI} + \text{P}$, some phosphoric and phosphorous acids, hydriodic acid, and ethyl iodide are simultaneously formed. J. B. Berthémot found that **antimony** or **bismuth** when heated with mercuric iodide and water furnishes bismuth oxyiodide in the one case, and antimonite oxide in the other. K. Haack states that mercuric iodide is not affected by boiling with soln. of **sodium hydrogen phosphate** or **arsenate**, or by fusion with either of these salts. M. Kohn found arsenious oxide in alkaline soln. reduces mercuric iodide. According to B. E. Howard, when treated with **hypophosphorous acid**, hydriodic acid is produced in which mercurous iodide is dissolved, and the reduction is incomplete.

J. B. Berthémot studied the action of various metals on mercuric iodide; he found that many of the heavy metals, alone or with water, withdraw all or half the iodine from mercuric iodide, and that the resulting metal iodide may or may not unite with part of the mercury iodide to form double salts, iodo-mercuriates. When heated and triturated with mercuric iodide and water, **zinc** forms zinc iodide and zinc amalgam with the evolution of much heat; **cadmium** behaves similarly; **tin** decomposes slowly, and with half an hour's boiling, **tin** amalgam and stannic oxide are formed, but undecomposed mercuric iodide and stannic iodide are still present; **iron** forms mercurous iodide, and afterwards, if heat be applied, mercury and ferrous iodide are formed; **copper** gives a similar result; **lead** forms lead iodide and mercurous iodide; and **silver** behaves similarly. C. F. Rammelsberg rubbed up mercuric iodide with **potassium** and formed potassium iodide and mercury; the reaction is attended by the evolution of much heat. T. Fischer also noticed the decomposition of mercuric iodide, suspended in water by **magnesium** powder.

J. B. Berthémot found that mercuric iodide is decomposed by soln. of the alkali hydroxides, forming mercuric oxide and a soln. of a double iodide of mercury and the alkali metal; if the soln. of the alkali hydroxide be very dil., C. F. Rammelsberg says that mercuric oxyiodide separates out. J. B. Berthémot also says that when

mercuric iodide is boiled with a soln. of **potassium hydroxide**, mercuric oxide separates out, and a yellow soln. of a double salt of mercuric and potassium iodide is formed, which on cooling deposits crystals of mercuric iodide, and then greenish-yellow needles of potassium idomercuriate. An alcoholic soln. of potassium hydroxide acts similarly, but more readily. Soln. of **sodium, barium, and strontium hydroxides** act similarly; so does an alcoholic soln. of **calcium hydroxide** in alcoholic but not in aq. soln. **Magnesium or aluminium hydroxides** have no action; similarly also with **magnesium carbonate**. Aq. soln. of **sodium or potassium carbonate** do not decompose mercuric iodide, but alcoholic soln. do so. Mercuric iodide is soluble in soln. of many of the normal salts. R. H. Brett found it to be soluble in soln. of **ammonium nitrate**. Mercuric iodide dissolves in soln. of **mercuric chloride, acetate, or nitrate**, and, according to H. Morse, a litre of $N\text{-Hg}(\text{NO}_3)_2$ dissolves 48.0 grms. of mercuric iodide. M. François observed a reversible reaction between mercurous nitrate and mercuric iodide: $\text{HgI}_2 + 2\text{HgNO}_3 \rightleftharpoons \text{Hg}(\text{NO}_3)_2 + 2\text{HgI}$. G. C. Wittstein noted the ready solubility of mercuric iodide in a hot soln. of **ammonium sulphate** and **ammonium carbonate**; G. C. Wittstein, and H. Saha and K. N. Choudhuri, and R. Böttger in a cold soln. of **ammonium chloride**; P. F. G. Boullay, and M. C. Lea, in soln. of **potassium chloride, sodium chloride, calcium chloride, and barium chloride**. H. Grossmann found mercuric iodide to be very soluble in soln. of **ammonium bromide**, and F. Jander in soln. of **potassium iodide, potassium bromide, and ammonium iodide**, with the formation of complex salts—e.g. NH_4HgI_3 . P. Harth could find no signs of a reaction with potassium chloride or bromide when the soln. is extracted with ether. A soln. of mercuric iodide in potassium iodide was used by E. Sonstadt and A. von Lasaulx as a heavy liquid—*Sonstadt's heavy liquid*—for the separation of minerals of different sp. gr. M. François found that with **ammonium iodide** a balanced reaction: $\text{NH}_4\text{I} + \text{HgI}_2 \rightleftharpoons \text{NH}_4\text{HgI}_3$, is established. J. Philipp has studied the solubility of mercuric iodide in soln. of **potassium thiocyanate**, and isolated a double salt: $\text{HgI}_2 \cdot 2\text{KSCy} \cdot 2\text{H}_2\text{O}$. Mercuric iodide is also soluble in soln. of **potassium cyanide**; according to P. Harth, two mols of potassium cyanide completely decompose a mol of mercuric iodide into mercuric cyanide and potassium iodide as proved by extraction with ether. F. Labouré noted that when mercuric iodide is treated with a soln. of **stannic chloride**, it is decomposed with the loss of iodine, becoming yellowish-red, yellow, greenish-yellow, green mercurous iodide, and finally into a mixture of mercury and stannic iodide. Mercuric iodide forms a number of double salts with other metal chlorides, and also with a number of organic bases.¹⁵ A mixture of mercuric iodide with 96 per cent. of benzoated lard or suet is the *unguentum hydrargyri iodidi rubri* of the pharmacopœia which is

FIG. 29.—Freezing-point Curves of Mixtures of Mercuric Iodide and Chloride.

used as an ointment in some skin diseases. A mixed soln. of equal parts of arsenious and mercuric iodides is the *liquor arsenii et hydrargyri iodidi*, or *Donovan's solution* of the pharmacopœia.

H. Moissan¹⁶ suggested the bare possibility of **mercuric fluoriodide** being formed by the action of fluorine on mercuric iodide. According to J. S. van Nest, H. Köhler, and W. C. Luczizky, only a limited series of mixed crystals is formed between mercuric chloride and iodide. M. Padoa and C. Tibaldi's fusion curves, Fig. 29, show that α -mercuric iodide and mercuric bromide give a typical V-eutectic. The same diagram shows the effect of mercuric chloride on the transition point of mercuric iodide. The regions of mixed crystals are also indicated in the diagram. There are no signs of the formation of any mixed salts under these conditions. M. Berthelot found the heat of combination of the two salts is

almost zero. J. von Liebig prepared what has been considered to be *mercuric tetrachlorodi-iodide*, $2\text{HgCl}_2 \cdot \text{HgI}_2$, by crystallization during the cooling of a boiling aq. soln. of mercuric chloride sat. with the iodide; F. Selmi, and E. Riegel, likewise by boiling mercuric chloride and water with an excess of iodine. H. Köhler showed that the products are not chemical individuals. According to J. L. Lassaigne, a soln. of mercuric chloride sat. in the cold with mercuric iodide furnishes colourless needles with $\text{HgCl}_2 : \text{HgI}_2$ in the molar proportions 40 : 1; an aq. or alcoholic soln. of iodine nearly decolorized with mercuric chloride, deposits on evaporation a similar product. If the iodide be in excess the crystals appear red owing to the presence of mercuric iodide which may be removed by re-crystallization from water. The aq. soln. has the general reactions of mercuric chloride; it gives no blue coloration with starch even when chlorine or sulphur dioxide has been added. A soln. of mercuric chloride decolorizes blue iodide of starch, due, said N. A. E. Millon, to the formation of mercuric iodide and iodine chloride; the blue colour appears if potassium iodide is added, because the iodine chloride is decomposed. P. F. G. Boullay and A. Larocque prepared what has been regarded as *mercuric chloroiodide*, HgClI , or $\text{HgI}_2 \cdot \text{HgCl}_2$, as a yellow powder, by cooling a soln. of mercuric chloride sat. with the iodide. The product soon changes to a red colour; if the soln. of mercuric chloride be incompletely sat. with the iodide, it first deposits a yellow powder, then yellow crystals, which soon turn red. H. Köhler confirmed the preceding results, and said the best yield is obtained by heating 4.5 grms. of mercuric chloride with 2.5 grms. of iodine in a sealed tube at 140° – 160° , or by heating 4.5 grms. of mercuric iodide and 2.7 grms. of mercuric chloride with a little water in a sealed tube for 4–5 hrs. at 140° – 160° ; and M. Berthelot and S. de Luca, by allowing conc. hydrochloric acid to act on mercury in the presence of allyl iodide. The yellow form of this compound is in rhombic crystals, the red form in tetragonal prisms. According to H. Köhler, mercuric chloroiodide becomes citron-yellow at 125° , and melts at 153° to a golden-yellow liquid. It boils at 315° , and sublimes unchanged at a somewhat lower temp. It is very sparingly soluble in water, but rather soluble in hot alcohol. By chlorine it is converted into mercuric chloride with development of heat; it may be sublimed in a current of hydrochloric acid, sulphur dioxide, or hydrogen sulphide without decomposition, but in dry ammonia it falls to a grey powder. It is somewhat soluble in dil. hydrochloric acid, and from this soln. hydrogen sulphide does not precipitate black mercuric sulphide even when hot, but a voluminous greenish-yellow precipitate of mercuric chloroiodosulphide, Hg_2SClI , which is sensitive to light. An aq. soln. of mercuric chloroiodide is used as A. von Hübl's reagent for measuring the iodine number of fats. P. Welmans preferred a soln. in ethyl acetate. C. Böttinger found it gives yellow products when added to gallic acid or tannin soln. W. Reinders,¹⁷ W. C. Luczizky, J. S. van Nest found that fused mixtures of mercuric bromide and iodide, or crystals obtained from the aq. soln. furnishes a complete series of mixed crystals—*vide* Figs. 29 and 30. K. Beck measured the viscosity of the mixtures; and P. Niggli, the f.p. and sp. gr. M. Berthelot found that the heat of union of mercuric iodide and bromide is almost zero. The m.p. of mixed crystals with more than 25 per cent. of mercuric bromide was found by P. Niggli to be lowered by sulphur dioxide. The alleged *mercuric bromoiodide*, HgIBr , obtained by A. Oppenheim by the action of alkyl iodides on an acetone soln. of mercuric bromide, or by crystallization from ether or acetone soln. of the component salts, thus appears as one member of an unbroken series of mixed crystals. H. Grossmann prepared rhombic plates of **ammonium mercuric tribromotetraiodide**, $3\text{NH}_4\text{Br} \cdot 2\text{HgI}_2$, by saturating a cold conc. soln. of ammonium bromide with mercuric iodide, evaporating over sulphuric acid, and removing the crystals of ammonium bromide; the crystals

FIG. 30.—Fusion Curve of Mixtures of Mercuric Bromide and Iodide.

are dichroic, being yellow when viewed parallel and pale yellow when viewed perpendicular to the prism edges. The crystals are decomposed by water; he also obtained similar crystals of **ammonium mercuric dibromodiiodide**, $2\text{NH}_4\text{Br} \cdot \text{HgI}_2$, by concentrating on the water-bath a soln. of a mol of mercuric iodide in a conc. soln. of 2 mols of ammonium bromide.

According to R. Abegg and G. Bodländer's hypothesis of electro-affinity, the tendency of the mercuric halides to form complex cations is weaker the stronger the anion, combining with the mercuric ion to form the cation, since an increase in the electro-affinity of the halogen radicle should be accompanied by an increase in the tendency of the radicle to ionize according to the scheme $\text{HgX} \rightarrow \text{Hg}^{++} + \text{X}'$. V. Borelli has shown that this is the case with the complex salts formed by mercuric perchlorate with mercuric iodide, bromide, chloride, cyanide, and thiocyanide. Here the tendency to form complex ions is greatest with mercuric iodide and cyanide, less marked with the bromide, and so slight with the chloride that the double salt cannot be isolated. **Mercuric perchloratoiodide**, $\text{I} \cdot \text{HgClO}_4$, forms bundles or mammillary masses of white, opaque prisms which deliquesce and turn yellow in air, and are decomposed by water with the liberation of mercuric iodide. The lowering of the f.p. in water gives values for the mol. wt. less than that calculated for the complete ionization and for the partial hydrolysis of the perchlorate: $\text{Hg}(\text{ClO}_4)_2 + \text{H}_2\text{O} = \text{HClO}_4 + \text{Hg}(\text{OH})\text{ClO}_4$, studied by H. Ley and C. Heimbucher. The depression of the f.p. of water by mercuric perchlorate is diminished by mercuric iodide, and this the more the greater the proportion of iodide present in the soln. Accordingly, the molar conc. of the complex undergoes a corresponding decrease. The lowering of the conductivity of mercuric perchlorate soln. by addition of potassium iodide is due to a decrease in the conc. of the ions, and to the lower mobility of the new ions. The addition of mercuric iodide produces an increase in the molar conc. of mercuric perchlorate soln. when this is not excessively conc., and a decrease when an excess of the perchlorate is present. V. Borelli attributed these results to various reactions between mercuric iodide and the ions Hg^{++} and ClO_4' originally present in the soln. Mercuric iodide probably unites with the Hg^{++} -ions to give complex cations, a view in harmony with measurements of the transport numbers of soln. of mercuric iodide containing an excess of the perchlorate.

§ 25. Ammino-, Ammino-basic, and Aquo-amminobasic Salts of Mercuric Iodide

According to G. Gore,¹ E. C. Franklin and C. A. Kraus, and H. P. Cady, mercuric iodide is soluble in liquid ammonia. According to E. C. Franklin, the soln. in liquid ammonia suffers amminolysis, $2\text{HgI}_2 + 4\text{NH}_3 \rightleftharpoons \text{Hg} : \text{N.HgI} + 3\text{NH}_4\text{I}$, and M. François represents the hydrolysis with conc. aqua ammonia as occurring in two stages, $\text{HgI}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{NH}_2\text{HgI} + \text{NH}_4\text{I}$, and $2\text{NH}_2\text{HgI} \rightleftharpoons \text{Hg} : \text{N.HgI} + \text{NH}_4\text{I}$; if dil. aqua

ammonia be used, a compound $\text{Hg}_9\text{N}_4\text{I}_6$ is formed. According to R. Böttger, when aq. ammonia acts on mercuric iodide, a brown powder—probably $\text{NH}_2\text{Hg.O.HgI}$ or $\text{NHg}_2\text{I.H}_2\text{O}$ —is formed along with a yellow liquid; G. C. Wittstein says that aq. ammonia turns mercuric iodide white, and later, when heated, it forms brownish-red powder—probably $\text{NH}_2\text{Hg.O.HgI}$. According to F. M. G. Johnson and N. T. M. Wilsmore, the soln. of mercuric iodide in aqua ammonia, sp. gr. 0.880, does not freeze at the m.p. of liquid ammonia. A. Cailliot and M. Corriol found that when the soln. obtained by treating mercuric iodide with aq. ammonia is evaporated in air, white needle-like crystals of **mercuric monamminiodide**, $\text{HgI}_2.\text{NH}_3$, are formed. C. F. Rammelsberg supposed it to be $\text{HgI}_2(\text{NH}_3)_2\text{HgI}_2$; and L. Pesci, $8\text{NH}_4\text{I.4HgI}_2.3\text{NHg}_2\text{I}$. C. F. Rammelsberg says that a similar product is formed by allowing aq. ammonia to act upon mercuric iodide until a white powder is formed, and J. Nessler added that if conc. aq. ammonia be used, the diammino-compound is formed. C. F. Rammelsberg made the monammino-compound by precipitation from a soln. of mercuric iodide in an alkali thioantimonate by the addition of aq. ammonia; and J. Nessler obtained it by treating a soln. of a mol of mercuric iodide and two of potassium iodide with aqua ammonia; if an excess of ammonia be used, the diammino-compound is formed. The monammino-salt loses its ammonia rapidly in air and still more rapidly under water or dil. acids—mercuric iodide remains.

According to H. Rose, 100 parts of mercuric iodide absorb 7.01 parts of ammonia, forming **mercuric diamminiodide**, $\text{HgI}_2.2\text{NH}_3$; the dirty white product loses its ammonia in a few hours on exposure to air and reforms red mercuric iodide. W. Peters, H. Ley and G. Wiegner also found that by exposing mercuric iodide to the action of ammonia gas in a eudiometer two mols are absorbed, and that the absorbed gas is given off in vacuo. M. François, and A. Colson also made the same compound by the action of dry ammonia on dry red mercuric iodide; A. Colson made it by passing dry ammonia through a soln. of mercuric iodide in dry benzene; L. Pesci, by adding aqua ammonia sat. at 0° to a soln. of mercuric iodide in potassium or ammonium iodide; P. Lemoult, by saturating a soln. of potassium tetraiodomercuriate, K_2HgI_4 , with conc. aqua ammonia and cooling to 0° ; J. Nessler, by treating the monoammino-compound with conc. aqua ammonia, or ammonia gas; and J. Nessler, H. Saha and K. N. Choudhuri, by the action of a cold sat. soln. of ammonia on mercuric iodide, or, according to M. François, on mercurous iodide.

C. F. Rammelsberg represented this compound by the formula $(\text{NH}_3)_2\text{HgI}_2$, and T. Weyl, by $2\text{NH}_4\text{I.NHg}_2\text{I}$. It forms a colourless or pale yellow powder or needle-like crystals which are very unstable, so that when removed from the mother liquor, the crystals soon redden owing to the loss of ammonia and the formation of red mercuric iodide; according to H. Saha and K. N. Choudhuri, the crystals are stable in an atm. of ammonia. According to M. François, the dissociation takes place in two stages: **mercuric tetramminohexaiodide**, $3\text{HgI}_2.4\text{NH}_3$, is first formed: $3\text{HgI}_2(\text{NH}_3)_2 \rightleftharpoons 3\text{HgI}_2(\text{NH}_3)_4 + 2\text{NH}_3$; and the product then decomposes: $3\text{HgI}_2(\text{NH}_3)_4 \rightleftharpoons 3\text{HgI}_2 + 4\text{NH}_3$. The dissociation pressures are:

$3\text{HgI}_2(\text{NH}_3)_2 \rightarrow 3\text{HgI}_2.4\text{NH}_3 + 2\text{NH}_3$					$3\text{HgI}_2.4\text{NH}_3 \rightarrow 3\text{HgI}_2 + 4\text{NH}_3$			
Temp. . . .	0°	25°	55°	80°	15°	25°	55°	95°
Press. mm. .	8	37	219	732	1	2	12	107

Mercuric diamminiodide is decomposed completely by water, and mercuric iodide is formed. M. François says the diammino-compound is insoluble in a little ammonia but soluble in a large quantity. Aq. ammonia forms first a yellow soln. which turns brown, and, according to J. Nessler, deposits brown $\text{NH}_2\text{Hg.O.HgI}$; and, according to L. Pesci, if small portions are added to a large excess of ammonia, NHg_2I is formed. M. François says that with conc. ammonia, NHg_2I is formed, and that the reaction is reversible; and that with less ammonia NH_2HgI is formed by a reversible reaction. L. Pesci says that hydrogen sulphide converts mercuric diamminiodide suspended in water into mercuric sulphide and a soln. of ammonium iodide; according to

M. François, ether dissolves the diammino-compound completely; but, according to J. Nessler, ether dissolves it only partially, alcohol also dissolves it partially, forming a yellow or, with more alcohol, a brown mass. If the dil. ethereal soln. be added to a soln. containing free aluminate, or zincate, a yellow coloration is obtained—the presence of potassium cyanide, sulphide, or iodide hinders the coloration; no coloration is obtained with alkali bicarbonate, potassium stannate, borax, or sodium phosphate. F. Ephraim and P. Mosimann made **mercuric zinc tetramminotetraiodide**, $[\text{Zn}(\text{NH}_3)_4]\text{HgI}_4$; **mercuric cadmium tetramminotetraiodide**, $[\text{Cd}(\text{NH}_3)_4]\text{HgI}_4 \cdot 4\text{H}_2\text{O}$; and **mercuric cadmium hexamminotetraiodide**, $[\text{Cd}(\text{NH}_3)_6]\text{HgI}_4 \cdot 6\text{H}_2\text{O}$.

M. François² prepared the iodine analogue of infusible white precipitate, **mercuric iodoamide**, NH_2HgI , by the action of conc. aqua ammonia added slowly and at long intervals on mercuric diamminiodide, $\text{Hg}(\text{NH}_3)_2\text{I}$. The precipitate was dried in an atm. of ammonia. If large quantities of aqua ammonia are added at once, brown dimercuriammonium iodide, Hg_2NI , is formed. The reaction is reversible, $\text{HgI}_2 \cdot 2\text{NH}_3 \rightleftharpoons \text{NH}_2\text{HgI} + \text{NH}_4\text{I}$, and with aq. ammonia of sp. gr. 0.923, at 21°, the conc. of the ammonium iodide, at equilibrium, was between 0.020-*N* and 0.023-*N*. Mercuric iodoamide forms a dirty white crystalline mass which is not reddened in air, and which is insoluble in ether. E. C. Franklin says that mercuric iodoamide may be also regarded as a basic mixture, $\text{Hg}(\text{NH}_2)_2 \cdot \text{HgI}_2$. M. François regards what has been called mercuric iodoamide, NH_2HgI , as monomercuriammonium iodide, and he gives for the graphic formulæ of this compound and mercuric diamminiodide, $\text{Hg}(\text{NH}_3)_2\text{I}_2$, and dimercuriammonium iodide, $\text{Hg}:\text{N}:\text{HgI}$,

As previously indicated, M. François found that if conc. aqua ammonia acts on mercuric diamminiodide, or on mercuric iodide **dimercuriammonium iodide**, Hg_2NI , or $\text{Hg}:\text{N}:\text{HgI}$, is formed. M. François also prepared this compound by the action of alkali hydroxide on mercuric diamminiodide.

Carefully stir 30 grms. of mercuric iodide in a glass mortar with 30 c.c. of aqua ammonia of sp. gr. 0.923, add 30 c.c. of ammonia, and stir the mixture 24 hrs. in a mortar with 90 c.c. of a 25 per cent. soln. of sodium hydroxide. Let the mixture stand under a bell jar with occasional stirring for five days. Draw off the liquid and again treat the solid with 90 c.c. of the 25 per cent. soda-lye, and heat the mixture for 2 hrs. on a water-bath. Wash by decantation with water, and dry at 50°.

T. Weyl first made it by the action of liquid ammonia on the basic iodide, $3\text{HgO} \cdot \text{HgI}_2$, and dried the product in a stream of dry air, first at 100° and then at 130°, and he says that he was not successful in his attempts to make it from $(\text{NH}_4)_2\text{O}$. E. C. Franklin also showed that this compound is formed by the aminolytic action of liquid ammonia on mercuric iodide, as well as by the action of potassium amide on an excess of mercuric iodide in soln. in liquid ammonia. The salt forms a dark red almost black crystalline powder or a dark brown powder which is very stable. It decomposes without explosion when heated in a tube—mercury and mercuric iodide sublime. It burns with a blue flame. It decomposes with the evolution of ammonia when boiled with a soln. of potassium hydroxide or chloride; it is insoluble in water, but soluble in hydrochloric acid. Dil. hydrochloric acid converts it into a mixture of mercuric iodide and chloride, and ammonium chloride. It is soluble in aq. soln. of ammonium chloride. Mercuric diamminiodide can be formulated as if it were a compound of ammonium and dimercuriammonium iodides, $3\text{NH}_4\text{I} \cdot \text{NH}_2\text{HgI}$.

A compound with the empirical composition $\text{Hg}_2\text{NH}_2\text{OI}$ —the yellow precipitate formed by the action of J. Nessler's reagent on ammoniacal compounds—has been the subject of many investigations. E. C. Franklin regards it as **mercuric**

hydroxyiodoamine, HgOH.NH.HgI , *i.e.* the iodide of Millon's base; and it can be regarded as $\text{Hg}(\text{HgOH})\text{NI}$, graphically:

as *oxydimercuriammonium iodide*, $\text{NH}_2(\text{Hg.O.Hg})\text{I}$, or as hydrated *dimercuriammonium iodide*, $\text{Hg}_2\text{NI.H}_2\text{O}$, but M. François could only prepare the anhydrous Hg_2NI .

According to E. C. Franklin, this compound is formed by the action of ammonia on mercuric iodide, and, in general, when mercuric iodide and ammonia are brought together in alkaline soln. For example, C. F. Rammelsberg, and T. Weyl made it by passing ammonia gas over 3HgO.HgI_2 at 180° ; C. F. Rammelsberg treated mercuric iodide with an excess of conc. aqua ammonia at 60° ; the red iodide becomes white, brown, and finally reddish-brown: $4\text{NH}_3 + 2\text{HgI}_2 + \text{H}_2\text{O} = 3\text{NH}_4\text{I} + \text{Hg}_2\text{NH}_2\text{OI}$; the supernatant liquid is decanted off, and the solid is washed by heating it seven times with fresh aqua ammonia. J. Nessler washed the precipitate finally with ether. J. Nessler prepared the same product by treating an aq. soln. of potassium iodomercuriate with potassium hydroxide and ammonia; if a little alkali hydroxide be used the product is pale yellow and the colour darkens more and more as the amount of alkali is increased: $2\text{K}_2\text{HgI}_4 + 3\text{KOH} + \text{NH}_3 = 7\text{KI} + 2\text{H}_2\text{O} + \text{Hg}_2\text{NH}_2\text{OI}$. L. Cramer obtained an emulsion by using soln. containing gum arabic or gelatine. C. F. Rammelsberg also converted the corresponding chloro-compound into the iodo-compound by digesting it with potassium iodide.

C. F. Rammelsberg reported that mercuric hydroxyiodoamide is a brown powder with a purple-red tinge. It loses a little hygroscopic moisture when heated to 128° , and when strongly heated in a retort, out of contact with air, it fuses to a brown liquid, which afterwards detonates with a blue light, and gives off mercury, mercuric iodide, ammonia, and nitrogen. When heated to 100° in a stream of hydrogen chloride, it appears dotted with yellow sparks, and emits white fumes; and if heated to the m.p., a sublimate is formed of mercuric aminoiodide, mercuric and ammonium chlorides, and ammonium iodide. The formation of water was not observed. According to H. B. Weiser, the iodide of Millon's base decomposes as low as 160° , but the reaction is not rapid until about 400° . The decomposing salt exhibits a luminescence more distinctly violet than the potassium flame. He added that the orange luminescence of mercury salts is due to the reaction $\text{Hg}^+\text{-ions} \rightarrow \text{undissociated mercurous salts}$; the green luminescence to the reaction $\text{Hg}^+\text{-ions} \rightarrow \text{Hg}^{\cdot\cdot}\text{-ions}$; and the violet luminescence to the reaction $\text{Hg}^{\cdot\cdot} \rightarrow \text{Hg}$. If heated with an aq. soln. of barium sulphide—or, according to J. Nessler, potassium sulphide—the contained nitrogen is all evolved in the form of ammonia; it dissolves in a warm aq. soln. of potassium iodide giving off ammonia—the liquid contains potassium iodomercuriate, K_2HgI_4 , and free potassium hydroxide; mercuric hydroxyiodoamide, dissolves in hydrochloric acid, forming a colourless liquid which on cooling deposits crystals of mercuric iodide and mercuric chloroiodide; it is not decomposed by boiling potash-lye, and no ammonia is therefore given off under these conditions.

The compound **enneamercuriammonium iodide**, $\text{Hg}_9\text{N}_4\text{I}_6$, was made by M. François by the action of a $\frac{1}{10}\text{N}$ -soln. of ammonia on mercuric tetrammino-hexaiodide, $3\text{HgI}_2.4\text{NH}_3$. The white mass becomes brown. After standing 8 hrs., the supernatant liquid is decanted off; the solid washed with water, and dried in air. It is then washed by decantation with ether. The reaction is reversible and is represented: $3\text{Hg}_3(\text{NH}_3)_4\text{I}_6 + n\text{NH}_3 \rightleftharpoons \text{Hg}_9\text{N}_4\text{I}_6 + 12\text{NH}_4\text{I} + (n-4)\text{NH}_3$. This compound was also made by gradually heating mercuric iodoamide between 80° and 100° when the white mass becomes brown and ammonia is evolved: $12\text{NH}_2\text{HgI} = \text{Hg}_9\text{N}_4\text{I}_6 + 3\text{HgI}_2 + 8\text{NH}_3$; the reaction is not reversible. The same compound was made by the action of a 25 per cent. soln. of sodium hydroxide, on mercuric diamminoiodide. M. François represents the formula of $3\text{HgI}_2.4\text{NH}_3$, by

$\text{Hg}_3\text{H}_4\text{I}_{12}$, and he regards $\text{Hg}_9\text{N}_4\text{I}_6$ as being formed by replacing all the hydrogen by bivalent mercury, graphically :

in which two nitrogen atoms are supposed to be quinquivalent and two septivalent. M. François prepared microscopic crystals of $\text{Hg}_9\text{H}_4\text{I}_6$; and found it to be insoluble in neutral solvents, and to be transformed by conc. soda-lye into mercuric oxyiodide and dimercuriammonium iodide. M. François also prepared **heptamercuriammonium tetraiodide**, $\text{Hg}_7\text{H}_2\text{N}_4\text{I}_4$, by the action of 50 c.c. of $\frac{1}{10}\text{N}$ -ammonia on $3\text{HgI}_2 \cdot 4\text{NH}_3$ (eq. to 2.5 grms. of mercuric iodide) for two days with frequent stirring. The reaction is reversible. The brown crystalline mass is represented as being constituted :

L. Pesci attempted to prepare $\text{Hg}(\text{NH}_3)_2\text{I}_2$ by the action of ammonia on mercuric iodide; and of a soln. of ammonium carbonate on freshly precipitated mercuric iodide, but he obtained what he regarded as $8\text{NH}_4\text{I} \cdot 4\text{HgI}_2 \cdot 3\text{NH}_2\text{I}$, *ammonium-mercuri-dimercuriammonium iodide*, but which E. C. Franklin supposes to be a slightly ammonolyzed mixture, $\text{NH}_2 \cdot \text{Hg} \cdot \text{I} \cdot 9\text{Hg}(\text{NH}_3)_n\text{I}_2$.

According to M. Adams,³ hydroxylamine does not unite with mercuric iodide to form a complex **mercuric hydroxylamine iodide**; the reduction of mercuric oxide to mercury by hydroxylamine hydroiodide was so rapid, even in the cold, that no intermediate products were isolated. The other methods employed in the preparation of the double salts with hydroxylamine chloride and mercuric chloride are also without avail. Hence, the reducing power of hydroxylamine or its hydrochloride increases in passing from the chloride to the iodide.

§ 26. Double and Complex Salts of Mercuric Iodide—The Iodomercuriates

Mercuric iodide forms a series of double salts with the univalent metals $\text{M}'\text{HgI}_3$ and $\text{M}'_2\text{HgI}_4$ —according to D. Dobrosserdoff,¹ the former are decomposed by water,

but the latter are fairly stable. The bivalent metals form salts of the types $M''Hg_2I_6$ and $M'HgI_4$. These double salts are supposed to be salts of the complex acids $HHgI_3$, H_2HgI_4 , $H_2Hg_2I_6$. A. Kekulé says that hydrogen sulphide gives no precipitate when passed into a conc. soln. of mercuric iodide in hydriodic acid. According to M. Berthelot, the heat developed during the action of hydriodic acid on mercuric iodide makes it probable that **hydriodomercuric acids** are formed; thus, $HgI_2 + 4HI = 5.6$ Cals., and $HgI_2 + 8HI = 5.8$ Cals. Nearly the same amount of heat is developed as by the soln. of mercuric iodide in a soln. of potassium iodide and as is the case when hydriodic acid reacts with potassium hydroxide. P. F. G. Boullay dissolved a mol of mercuric iodide in one of warm hydriodic acid; on cooling, crystals of mercuric iodide were first deposited, and these were followed by a crop of citron-yellow transparent needles. The crystals are probably $3HgI_2 \cdot 2HI \cdot H_2O$, because M. François obtained these crystals by an analogous process. The crystals give off hydriodic acid, forming mercuric iodide when exposed to warm dry air; they are decomposed by water, forming mercuric iodide. G. Neumann evaporated a sat. soln. of mercuric iodide in hydriodic acid in a desiccator over sulphuric acid and lime at the temp. of a winter's cold. The resulting yellow needles had the composition $HgI_2 \cdot HgI$, and they became red when exposed to the air.

Four double mercuric and ammonium iodides have been prepared with the ratios $HgI_2 : NH_4I : H_2O$ as 2 : 1 : 0, 1 : 1 : 1, 1 : 2 : 0, and 1 : 2 : 1. P. F. G. Boullay² found that a hot aq. soln. of a mol of ammonium iodide dissolves one and a half mols of mercuric iodide; part of the latter separates out on cooling, and the remaining liquid furnishes crystals of **hydrated ammonium triiodomercuriate**, $NH_4I \cdot HgI_2 \cdot H_2O$, or $NH_4HgI_3 \cdot H_2O$. A. Longi and G. Mazzolino also prepared the same salt from one part of a mixture of two mols of iodoform and three mols of mercuric cyanide with four of five parts of alcohol treated in a sealed tube for two days at 150°–155°, or for a shorter time at 160°–165°. Hydrogen cyanide, carbon monoxide, carbon dioxide, methane, formic acid, mercury, etc., are formed. The yellow oil also produced smells of an isonitrile, and furnishes on evaporation crystals of $NH_4I \cdot HgI_2 \cdot H_2O$ which can be purified by recrystallization from alcohol. F. Pfankuch previously obtained these crystals, but regarded them as a double compound of cyanoform and mercuric iodide, $2CHCy_3 \cdot 3HgI_2$, a conclusion which A. Claus could not verify. Hydrated ammonium tri-iodomercuriate crystallizes in yellow needles, which are stable in air, but, according to P. F. G. Boullay, in vacuo they become orange-yellow and give off 3 per cent. of water; and when heated, also, they fuse to a yellow liquid, which gives off 3 per cent. of water, and then becomes viscid and acquires a red colour—on cooling, the mass freezes to an anhydrous mass of red crystals. If heated to a still higher temp., part of the salt sublims undecomposed, and part is resolved into mercury, mercuric iodide, etc. A. Longi and G. Mazzolino give the m.p. as 110°–111°, and say that the liquid freezes to a mass of yellow needles at 75°; they also add that the crystals lose water in open vessels at 100°, or in a stream of dry air at 65°–70°, and become orange-red. Water decomposes the crystals with the separation of 40 per cent. of mercuric iodide, and P. F. G. Boullay adds that the remaining soln. contains an excess of ammonium iodide, for it yields crystals of hydrated ammonium tri-iodomercuriate when conc. by evaporation; A. Longi and G. Mazzolino obtained crystals of approximately the composition $12NH_4I \cdot 5HgI_2$, but it is not clear if this formula is that of a compound or a mixture—probably the latter. According to M. François, in the action of water on ammonium triiodomercuriate, there is a state of equilibrium which alters with temp. less mercuric iodide separates the higher the temp. of the water, and with a large proportion of water a soln. of mercuric iodide in ammonium iodide is formed, while with a small proportion of water, a soln. of ammonium triiodomercuriate in ammonium iodide is formed. A. Longi and G. Mazzolino say that ammonium triiodomercuriate is soluble in alcohol, and rather more soluble in ether; and that when this salt is treated with an alkali hydroxide or sulphide, ammonia is evolved.

A. Ferratini prepared **hydrated dihydrazine triiodomercuriate**, $2\text{N}_2\text{H}_4 \cdot \text{HI} \cdot \text{HgI}_2 \cdot \text{H}_2\text{O}$, by the action of powdered mercuric iodide on a conc. soln. of the hydrazine salt. After standing two days in vacuo, the soln. deposits yellowish-white, prismatic, hygroscopic plates, which slowly decompose with the separation of mercuric iodide. The crystals melt at $92^\circ\text{--}93^\circ$, and the dark yellow fluid solidifies and melts a second time at $152^\circ\text{--}153^\circ$. This salt is but sparingly soluble in water, alcohol, acetone, ethyl acetate, etc.; and insoluble in ether. The aq. soln. are stable only if a very small proportion of water is present, and the salt very pure. The salt is vigorously attacked by conc. nitric acid.

S. Hajnóci and M. Löw prepared **ammonium pentaiododimercuriate**, $\text{NH}_4\text{I} \cdot 2\text{HgI}_2$, or $\text{NH}_4\text{Hg}_2\text{I}_5$, by heating a mixture of a mol of mercuric chloroamide with three of methyl iodide in a sealed tube for 10 to 12 hrs. at 100° . This salt forms an aggregate of light yellow crystals which can be separated from the mercuric methyl monamminiodide, $\text{HgI}_2(\text{CH}_3)\text{NH}_2$, and other products by fractional crystallization from nitrobenzene. When gently warmed in a sealed tube mercuric iodide sublimes, and with stronger heating ammonia gas is evolved. Water decomposes the salt with the separation of mercuric iodide; and it is soluble in an aq. soln. of potassium iodide; and very soluble in alcohol, ether, and nitrobenzene.

A. G. Duboin made a heavy liquid of sp. gr. 2.98 (26°) and refractive index 1.527—sodium light—by alternately adding mercuric and ammonium iodides to a small quantity of water until sat. The soln. deposits crystals of **hydrated ammonium tetraiodomercuriate**, $2\text{NH}_4\text{I} \cdot \text{HgI}_2 \cdot \text{H}_2\text{O}$, or $(\text{NH}_4)_2\text{HgI}_4 \cdot \text{H}_2\text{O}$. H. St. C. Deville and L. Troost found the vapour density of $2\text{NH}_4\text{I} \cdot \text{HgI}_2$ to be 6.49 at 360° , and 6.38 at 440° . A. G. Duboin³ prepared a heavy liquid of sp. gr. 3.28 at 25.63° , and refractive index 1.783—sodium light—by alternately adding mercuric and lithium iodides to a small quantity of water until sat. The soln. gives a precipitate of mercuric iodide with water, but is soluble in alcohol. On standing, the soln. deposits **hexahydrated lithium tetraiodomercuriate**, $2\text{LiI} \cdot \text{HgI}_2 \cdot 6\text{H}_2\text{O}$, or $\text{Li}_2\text{HgI}_4 \cdot 6\text{H}_2\text{O}$, in the form of long, flattened, deliquescent needles, having a sp. gr. 3.26 at 0° , readily soluble in methyl, ethyl, propyl, isopropyl, isobutyl, amyl, or allyl alcohol, glycerol, acetaldehyde, acetone, formic or acetic acid, ethyl acetate, or oxalate, or ether; less soluble in nitrobenzene, ethylene bromide, or chloroform; insoluble in benzene or methyl iodide; and decomposed by water. The mother liquor from which the crystals have been removed yields at 8° a second **octohydrated lithium tetraiodomercuriate**, $\text{Li}_2\text{HgI}_4 \cdot 8\text{H}_2\text{O}$, or $2\text{LiI} \cdot \text{HgI}_2 \cdot 8\text{H}_2\text{O}$, in the form of large, soft, prismatic crystals, melting in the hand, having a sp. gr. 2.95 at 0° , closely resembling the first compound in solubility, but insoluble in ethylene bromide and almost so in nitrobenzene. F. Calzolari and U. Tagliavini prepared the hexamethylenetetramine derivative of A. G. Duboin's salt. J. E. Marsh prepared a number of compounds of mixed lithium halogenomercuriates with ethyl ether—e.g. $\text{LiBr} \cdot \text{HgBr}_2 \cdot 4(\text{C}_2\text{H}_5)_2\text{O}$; $\text{LiBr} \cdot \text{HgCl}_2 \cdot (\text{C}_2\text{H}_5)_2\text{O}$; $\text{LiCl} \cdot \text{HgBr}_2 \cdot (\text{C}_2\text{H}_5)_2\text{O}$; $\text{LiI} \cdot \text{HgI}_2 \cdot 6(\text{C}_2\text{H}_5)_2\text{O}$; $\text{LiI} \cdot \text{HgBr}_2 \cdot 5(\text{C}_2\text{H}_5)_2\text{O}$; $\text{LiBr} \cdot \text{HgI}_2 \cdot 4(\text{C}_2\text{H}_5)_2\text{O}$.

According to P. A. von Bonsdorff,⁴ the evaporation of an aq. soln. of sodium iodide sat. with mercuric iodide over sulphuric acid in a desiccator furnishes deliquescent yellow rhombic prisms of a double iodide of sodium and mercury whose composition was not determined but was possibly, $2\text{NaI} \cdot \text{HgI}_2$. About the same time, P. F. G. Boullay noted that a hot soln. of two mols of sodium iodide in a little water dissolves over three mols of mercuric iodide, and on cooling some of the latter separates out. The evaporation of the mother-liquid gives a yellow mass which is not crystalline, and which probably contains some yellow mercuric iodide, because when the inner surface of the basin is scratched with a glass rod, red mercuric iodide appears to be formed; if this be dissolved in warm water, more mercuric iodide separates out on cooling, and the mother liquid, when evaporated slowly, gives deliquescent needle-like crystals—probably **sodium tetraiodomercuriate**, $2\text{NaI} \cdot \text{HgI}_2$, but no analyses were given. J. B. Berthemot attempted to make the double salt by boiling mercuric iodide with aq. or alcoholic sodium

hydroxide, or sodium carbonate; or by boiling mercuric or mercurous oxide with aq. sodium iodide he obtained a deliquescent mass, but not definite crystals.

A. G. Duboin prepared a heavy liquid of sp. gr. 3.46 at 26°, and refractive index 1.797—sodium light—by alternately adding mercuric and sodium iodides to a small quantity of water until sat. The soln. absorbs a little moisture from the air, and gives a precipitate of mercuric iodide when mixed with a large proportion of water; the liquid is soluble in alcohol, aldehyde, acetone, formic acid, acetic acid, propionic acid, butyric acid, valeric acid, ethyl benzoate; and insoluble in benzene, monochlorobenzene, chloroform, ethylene bromide, and ethyl nitrate. Cellulose swells up and becomes transparent when placed in this liquid, and when the product is washed with an aq. soln. of sodium iodide, it dries to a horny mass. When A. G. Duboin's soln. is very slowly—"some weeks"—evaporated in dry air, it furnishes deliquescent flattened crystals of **tetrahydrated sodium tetraiodo-mercuriate**, $2\text{NaI} \cdot \text{HgI}_2 \cdot 4\text{H}_2\text{O}$, which have a sp. gr. of about 3 at 0°. E. Rupp prepared the anhydrous salt, $2\text{NaI} \cdot \text{HgI}_2$, by the action of an alkaline soln. of iodine on mercuric cyanide.

P. F. G. Boullay found that a boiling soln. of two mols of potassium iodide dissolved three mols of mercuric iodide, and deposited on cooling one mol of

mercuric iodide, but not so much in the presence of alcohol. A. Souville and F. Labouré⁵ got over two, but not so much as three mols of mercuric iodide in a soln. with two mols of potassium iodide, and it was therefore argued that the compound $2\text{KI} \cdot 3\text{HgI}_2$ is not formed in the soln., but that mercuric iodide is dissolved in a soln. of $\text{KI} \cdot \text{HgI}_2$, since on evaporation it yields needle-like crystals of this salt and cubes of potassium iodide. C. J. Tanret found that a soln. of 10 grms. of potassium iodide in 100 grms. of water dissolved 14.73 grms. of mercuric iodide at 20°. M. François noted a break in the solubility curve of mercuric iodide in soln. of potassium iodide, as illustrated in Fig. 31, which represents as abscissæ the number of grams of potassium iodide per 100 c.c. of liquid; likewise with

FIG. 31.—Effect of Potassium Iodide on the Solubility of Mercuric Iodide.

mercuric iodide as ordinates. A selection of his numbers, at 20°, is:

KI . . .	8.665	30.440	52.436	62.814	63.036	71.427	82.746	94.104
HgI ₂ . .	13.72	55.09	94.09	116.45	116.22	120.76	131.88	145.7

The break, A, in the curve for 62.8 grms. of potassium iodide and 116.2 grms. of mercuric iodide is attributed to the change in the solid phase from HgI_2 to $\text{KI} \cdot \text{HgI}_2$.

The solubility of mercuric iodide in aq. soln. of potassium iodide has been long explained by assuming that a soluble double or complex salt is formed. M. S. Sherrill examined the nature of the complex salts (i) from measurements of the e.m.f. of conc. cells of the type $\text{Hg} | \text{HgI}_{2\text{soln. } a} \cdot \text{HgI}_{2\text{soln. } b} | \text{Hg}$; (ii) from the effect of mercuric iodide on the f.p. of soln. of potassium iodide; (iii) from the distribution of mercuric iodide between benzene and aq. soln. of potassium iodide; G. Bredig and J. H. Walton (iv) from the effect of mercuric iodide on the catalytic decomposition of hydrogen peroxide by soln. of potassium iodide on the assumption that the velocity of the decomposition is proportional to the conc. of iodine-ions which is diminished in the presence of mercuric iodide; H. M. Dawson (v) from the partition of mercuric iodide between water and carbon disulphide or carbon tetrachloride; E. Rieger (vi) from the conductivity of soln. of potassium mercuric iodide being smaller than the sum of the conductivities of the constituents; and R. Abegg, C. Immerwahr, and F. Jander (vii) from the solubility of mercuric iodide in soln. of potassium iodide, where the mol. ratio $\text{KI} : \text{HgI}_2$ for soln. sat. with

mercuric iodide falls from 2.2 for a 0.031*N*-soln. to 1.82 for a *N*-soln. of potassium iodide. The general conclusion is that the soln. contain the complexes $2\text{KI} \cdot \text{HgI}_2$ and $3\text{KI} \cdot 2\text{HgI}_2$. Expressing the components in the order $\text{HgI}_2 : \text{KI} : \text{H}_2\text{O}$, the five salts 1:1:0, 1:1:1, 1:1:1½, 2:1:0, and 2:1:2 have been reported.

A. C. Dunningham has studied the three-component system $\text{HgI}_2\text{—KI—H}_2\text{O}$ at 20° and at 30°, and his results are plotted in Fig. 32. There is no evidence of

the formation of mixed crystals with potassium and mercuric iodides; and the following four solid phases, KI, KHgI_3 , $\text{KHgI}_3 \cdot \text{H}_2\text{O}$, and HgI_2 , were alone found to exist in equilibrium with the soln. The point *E* represents water; *F*, potassium iodide; *G*, mercuric iodide; *M*, potassium triiodomercuriate, KHgI_3 ; and *N*, monohydrated potassium triiodomercuriate, $\text{KHgI}_3 \cdot \text{H}_2\text{O}$. The line

AB represents the range of sat. soln. coexisting with solid potassium iodide; *BC*, with solid potassium triiodomercuriate; *CD*, with solid hydrated potassium triiodomercuriate; and *DE*, with solid mercuric chloride. The point *B* represents a sat. soln. coexisting with solid potassium iodide and triiodomercuriate; *C*, with solid potassium triiodomercuriate and its monohydrated salt; and *D*, with solid hydrated potassium triiodomercuriate and mercuric iodide. The area *FAB* represents mixtures of the sat. soln. on *AB* and solid potassium iodide; *BCM*, on *BC* and solid

iodomercuriate; *CND*, on *CD* and solid hydrated potassium triiodomercuriate; *EDG*, on *DE* and solid mercuric iodide; *FBM*, mixtures of soln. *B* and solid potassium iodide and triiodomercuriate; *MCN*, soln. *C* and solid potassium iodomercuriate and its monohydrated salt; *NDG*, of soln. *D* and solid hydrated potassium triiodomercuriate and mercuric iodide; and *MNG*, solid mixtures of mercuric iodide, potassium triiodomercuriate and its monohydrate. When solid mercuric iodide is added to a sat. soln. of potassium iodide, represented by *A*, the composition of the mixture follows the line *AG*. The first solid phase which separates is hydrated potassium triiodomercuriate, $\text{KHgI}_3 \cdot \text{H}_2\text{O}$. A. C. Dunningham also studied the ternary systems: potassium iodide, ether, and water at 20°; mercuric iodide, ether, and water; and potassium and mercuric iodides and ether at 20°, and again found the range of the existence of potassium iodomercuriate, KHgI_3 , but of no other iodide. He also worked out the conditions of equilibrium of the four-component or quaternary system: mercuric and potassium iodides, ether, and water.

P. F. G. Boullay obtained crystals of **potassium triiodomercuriate**, $\text{HgI}_2 \cdot \text{KI}$, or KHgI_3 , by cooling a hot sat. soln. of mercuric iodide in potassium iodide until one-third the mercuric iodide which was in soln. had separated out; by further cooling the mother liquor, prismatic crystals of this salt were said to be formed. If mol. proportions of the component salts be used, W. A. H. Naylor and E. J. Chappel say that a mixture and not a compound is formed. P. A. von Bonsdorff evaporated a soln. of potassium iodide, sat. in the cold with mercuric iodide, in dry air, or over sulphuric acid in a desiccator, and obtained crystals of this salt; he also evaporated a soln. of mercuric chloride in potassium iodide until crystallization occurred, and extracted the double salt with alcohol—potassium chloride remained as an insoluble residue. J. B. Berthémot likewise prepared yellow crystals of this salt on cooling the liquid obtained by boiling mercuric iodide with alcoholic potassium hydroxide or carbonate; and also by boiling mercuric oxide with an aq. soln. of potassium iodide, so that the proportion of mercuric to potassium iodide is as 1:1, the liquid

FIG. 32.—A. C. Dunningham's Equilibrium Diagram for the Ternary System, $\text{HgI}_2\text{—KI—H}_2\text{O}$.

contains potassium hydroxide and deposits crystals of KI.HgI_2 . If mercurous oxide is used some mercury is formed, and if the oxide be in excess, some mercurous iodide as well. According to J. E. Marsh and R. de J. F. Struthers, this salt can be extracted from an aq. soln. of 2KI.HgI_2 by ether, ethyl formate, or other solvents.

Potassium triiodomercuriate forms long yellow prismatic crystals similar to the ammonium salt. M. Berthelot gives the heat of formation from red mercuric iodide as 2.1 Cals., and from the yellow, 5.1 Cals. P. F. G. Boullay says that when the salt is heated it loses a little water, and melts to a red liquid from which mercuric iodide sublimes. R. Brandes and G. Böhm said that if the temp. is not too high the molten liquid is yellow and solidifies to a greenish-yellow mass with a radiating fracture; at a higher temp. the liquid is brown, and the solid has a granular fracture; at a still higher temp. the molten salt is dark brown, and gives off mercuric iodide. The mol. lowering of the f.p. of aq. soln. was found by F. M. Raoult to be 90° . According to P. F. G. Boullay, water separates about half the mercuric iodide, and forms a soln. of 2KI.HgI_2 . This is probably a wrong inference. According to A. C. Dunningham's work, if water be added to potassium iodomercuriate, KHgI_3 , the composition of the mixture can be represented by points on the line ME , Fig. 32. When N is reached, all the salt is converted into hydrated potassium iodomercuriate; further additions of water cause the formation of soln. D with the two solid phases, mercuric iodide and hydrated potassium iodomercuriate; at P , all the last-named salt is decomposed and mercuric iodide alone appears as solid phase. The mixture then follows the line DE , more and more mercuric iodide being formed as the proportion of water increases, until, at E , the soln. is virtually pure water, for the solubility of mercuric iodide can, for the present purpose, be regarded as negligibly small. P. F. G. Boullay states that dil. acids separate all the mercuric iodide from potassium iodomercuriate. J. B. Berthelot and P. F. G. Boullay say that although conc. acetic acid dissolves neither of the component salts, it does dissolve the double salt, and the double salt also dissolves in ether; the addition of water to the alcoholic soln. precipitates mercuric iodide, but R. Brandes and G. Böhm said that the alcoholic soln. may be mixed with the ethereal soln. without precipitation; and that a soln. in 70 per cent. alcohol deposits crystals of mercuric iodide during spontaneous evaporation. A. C. Dunningham, and J. E. Marsh have made a special study of the action of ether on this salt—a double salt, $\text{KHgI}_3 \cdot 4(\text{C}_2\text{H}_5)_2\text{O}$, is formed. R. Brandes and G. Böhm also found the salt to be permanent in dry air, but hygroscopic in moist air; and if a thin film of the salt be formed on a watch-glass by the evaporation of its alcoholic soln., the colour is red when breathed upon, and the yellow colour is restored when gently heated. W. Pawloff found that the crystals sinter at 69° ; they become red at 72° – 80° ; and they begin to volatilize at 104.5° . The molten salt if shaken freezes at 105° , but otherwise it remains liquid down to 85° , when it solidifies and the temp. rises to 104.5° . The last traces of water are expelled at 191° – 193° , and it decomposes at 204° into its components; P. Walden and M. Centnerszwer say the salt melts at 117° to a red liquid, and that it loses over one per cent. in weight when heated to 98° , but the loss of weight is not constant because some mercuric iodide is lost by volatilization along with the water. M. Berthelot gives the heat of formation from red mercuric iodide as 2.3 Cals. and from the yellow iodide 5.3 Cals. According to P. F. G. Boullay, mercury distills from a heated mixture of potassium triiodomercuriate and copper or iron; chlorine decomposes the heated salt, and potassium chloride remains.

W. Pawloff prepared **hydrated mercuric triiodomercuriate**, $\text{KHgI}_3 \cdot \text{N}_2\text{O}$, by crystallization from a soln. of equimolar parts of the component salts evaporated in a desiccator; and when a mixture of the component salts is allowed to stand for a few weeks in contact with undried ether this double salt is formed. P. Walden and M. Centnerszwer crystallized the commercial salt from a boiling mixture of acetone and benzene, and evaporated the soln. slowly at ordinary temp. The lower deep-red layer of liquid furnishes crystals of this salt which can be dried at

ordinary temp. The crystals are straw-yellow hygroscopic prisms or needles. The limits of stability of the salt in contact with water are indicated in Fig. 32. All are agreed that the salt is decomposed by water; and J. E. Marsh says that when the yellow crystals are moistened with water they become red—presumably owing to the formation of red mercuric iodide, but he says that the crystals can be dissolved in a little water, and that the liquid obtained by heating the salt to 117° is a soln. of the salt in its water of crystallization. W. Pawloff found that the salt is not decomposed by dissolving it in alcohol or acetone. J. E. Marsh says that the salt is not very soluble in dried ether, but is easily soluble in undried ether; that the solubility is greater in cold than in warm ether; and that the soln. in ether is accompanied by the development of heat, and the formation of a compound, $\text{KHgI}_3 \cdot 4(\text{C}_2\text{H}_5)_2\text{O}$.

W. A. H. Naylor and E. J. Chappel claim to have made the sesquihydrated salt, $\text{KHgI}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$, by dissolving 45 grms. of mercuric iodide and 16.5 grms. of potassium iodide in 20 c.c. of boiling 90 per cent. alcohol. Yellow crystals of the salt separate out during the cooling of the filtered soln. E. G. Clayton also obtained similar crystals by allowing a conc. soln. of Nessler's reagent to stand for some time. The crystals were washed with alcohol and dried. M. François also obtained this same salt. There is, however, some doubt if this hydrate really exists.

P. F. G. Boullay assumed *potassium tetraiodomercuriate*, $2\text{KI} \cdot \text{HgI}_2$, or K_2HgI_4 , to be present in the liquid obtained by dissolving potassium triiodomercuriate in water, when he supposed that half the mercuric iodide separates out. On evaporation, the soln. furnished a yellow mass but no crystals; when treated with water, the yellow mercuric iodide remains undissolved, but is dissolved on shaking the mixture. Both A. Souville and F. Labouré showed that the soln. contains not the tetraiodomercuriate, but is rather a soln. of potassium iodide in one of potassium triiodomercuriate. W. Pawloff says that if the component salts are present in aq. soln. in the ratio $\text{HgI}_2 : 2\text{KI}$, crystals of the double salt, $\text{HgI}_2 \cdot 2\text{KI} \cdot 2\text{H}_2\text{O}$, are formed. S. M. Jörgensen has said that if a soln. of iodine in one of potassium iodide be shaken with mercury, part of the iodine forms insoluble mercurous iodide and the remainder goes into soln. as $2\text{KI} \cdot \text{HgI}_2$. J. M. Thomson and W. P. Bloxam say that this salt separates from a supersaturated soln. when seeded with needle-like crystals of mercuric iodide, but not with crystals of potassium iodide. E. Rupp made it by the action of hydrochloric acid and potassium iodide on mercuric cyanide or chloride; E. Rupp and W. F. Schirmer, by the action of potassium iodide on mercuric oxide, and they propose a method for determining mercuric oxide in ointments by dissolving the oxide in water containing 8–12 times its weight of potassium iodide, and titrating the soln. with $\frac{1}{10}N\text{-HCl}$, using methyl orange as indicator. L. L. de Koninck and J. Lebrun also base a method for the volumetric determination of mercuric chloride by titration with potassium iodide; the separation of mercuric iodide, say F. Auerbach and W. Plüddemann, begins when this double salt, $2\text{KI} \cdot \text{HgI}_2$, is formed: $\text{HgCl}_2 + 4\text{KI} = \text{HgI}_2 \cdot 2\text{KI} + 2\text{KCl}$; but there is a slight error owing to the separation of mercuric iodide before all the mercury salt required for the last-named reaction has been added; this is due to the secondary reaction, $\text{HgI}_2 \cdot 2\text{KI} + \text{HgCl}_2 \rightarrow 2\text{HgI}_2 + 2\text{KCl}$, which depends on the relative concentrations of the salts in soln., and for which a correction can be made. J. E. Marsh and R. de J. F. Struthers made this salt by the action of different ketones—acetone, diethylketone, acetophenone, etc.—on a soln. of mercuric iodide in cold potash-lye. R. G. van Name and W. G. Brown studied the equilibrium of soln. of potassium and mercuric iodides, and obtained evidence of the formation of the double salt $2\text{KI} \cdot \text{HgI}_2$.

The facts are not very definite as to the formation of $2\text{KI} \cdot \text{HgI}_2$, since most of them can be interpreted by assuming that soln. of mercuric iodide in potassium iodide are formed, and there is the very clear evidence of A. C. Dunningham that this salt does not exist in aq. soln. between 20° and 30° . Consequently, the reaction etc., said to be due to the formation and properties of this salt really refers to a

soln. or mixture of potassium iodide with potassium triiodomercuriate. For example, J. Thomsen gave the heat of soln. of a mol of mercuric iodide in two of potassium iodide as 3.45 Cals., and the heat of soln. of the salt in 800 mols of water, as -9.81 Cals. E. Rieger found the electrical conductivity of 0.214 mol of mercuric iodide and 0.782 mol of potassium iodide per litre to be 7.0×10^{-4} . R. Behrend studied the e.m.f. of aq. soln. of the salt. F. Bezold said that the salt is copiously soluble in methyl acetate, and that hydrogen sulphide does not change the soln.; dry ammonia produces no change; but hydrogen sulphide in the soln. sat. with ammonia produces a red precipitate of mercuric sulphide. E. Alexander and M. Hamers found a similar behaviour with soln. in ethyl acetate. By electrolyzing a soln. of the salt in liquid sulphur dioxide, L. S. Bagster and B. D. Steele obtained a precipitate containing sulphur on the cathode. J. M. Eder and G. Ulm warmed the aq. soln. for a long time with sodium thiosulphate at 80°, and obtained a voluminous precipitate—a mixture of mercurous iodide and mercuric sulphide. H. Wegelius and S. Kilpi removed iodine from the soln. by the addition of moist silver chloride, and they noted the formation of silver tetraiodomercuriate, Ag_2HgI_4 , which below 50° is yellow, and red above this temp. H. Ley and G. Wiegner prepared a white potassium diamminotetraiodomercuriate, $\text{K}_2\text{HgI}_4 \cdot 2\text{NH}_3$, by the action of ammonia gas on potassium tetraiodomercuriate. The compound loses its ammonia after seven hours' exposure in vacuo, and becomes red. W. Peters found the vapour tension rises from 17 mm. at 0° to 272 mm. at 55°. Numerous compounds of mercuric iodide with organic compounds have been reported—e.g. A. Naumann's compound with benzonitrile, $\text{KHgI}_5 \cdot 5\text{C}_6\text{H}_5\text{CN}$; etc.

F. Hofmeister has studied the action of this salt on albumen. C. J. Tanret recommended the salt K_2HgI_4 as a reagent for albumenoids; and F. L. Winckler, W. Delffs, J. E. de Vrij, W. R. Grove, F. F. Mayer, C. J. Tanret, F. A. Flückiger, G. Herkel, I. Guareschi, etc., have recommended the same reagent on account of the colour reactions it produces with alkaloids. G. Romijn⁶ has recommended the alkaline soln. as an oxidizing agent. An aq. soln. of potassium and mercuric iodides can be made with a sp. gr. 3.196, and glass floats on the liquid. The soln. has been recommended by A. H. Church, J. Thoulet, V. Goldschmidt, J. Joly, and others for separating a mixture of minerals above and below the sp. gr. of the liquid. According to V. Goldschmidt, the soln. is best prepared in the following manner:

Stir 305 grms. of mercuric iodide and 246 grms. of potassium iodide with as little water as is necessary for the soln. of the salts. The ratio $\text{KI} : \text{HgI}_2$ is as 1 : 1.239, and this proportion gives the best result. The liquid is evaporated on the water-bath until a piece of tourmaline, sp. gr. 3.1, floats on it, the liquid is allowed to cool, and its sp. gr. will be nearly 3.196 in winter, 3.17 in summer. Acicular crystals of a hydrated double salt separate on cooling; the precipitate can be dissolved in a few drops of water, or it can be filtered off, dissolved in water, and evaporated to the necessary concentration. If too much potassium iodide be used, crystals separate on the surface of the liquid; and if too much mercuric iodide be used, a mass of yellow needles separates; this can be dissolved in water, but red mercuric iodide is simultaneously deposited, and is dissolved by agitation with a soln. of potassium iodide.

The conc. soln. is decomposed by adding water, and red mercuric iodide is deposited, but redissolved on agitating the mixture. The sp. gr. changes on long standing owing to the absorption of moisture from the air. The sp. gr., *D*, of the soln. with *W* grms. of the solid salt to 100 grms. of water is:

<i>D</i>	2.940	2.717	2.243	1.873	1.546	1.247	1.193	1.139	1.091	1.0477
<i>W</i>	617.24	466.96	255.2	150.6	83.0	33.9	25.809	18.205	11.677	6.001

The soln. is not affected by exposure to light. H. S. Hatfield, however, found that if iron compounds be present, the reaction: $2\text{KI} + \text{O} + \text{Hg} + \text{H}_2\text{O} = 2\text{KOH} + \text{HgI}_2$, occurs in sunlight, since under these conditions iron compounds are strong catalytic agents. The soln. is decomposed by organic matter—filter paper, etc. The

liquid is poisonous, and attacks the skin. Metals—derived from the grinding apparatus, etc.—decompose the soln. with the separation of mercury. It is difficult to wash the heavy soln. from the particles of minerals, and some minerals—e.g. feldspar, chrysocoll, zeolites, clays, and colloids—decompose or adsorb the soln. very tenaciously. The conc. soln. are very viscid, and the viscosities have been measured by E. Clerici; and A. G. Duboin has measured the refractive indices—a soln. of sp. gr. 3.196 (22.9°) has a refractive index 1.730—for the Na-line.

An alkaline soln. of the double potassium and mercuric iodide—called **Nessler's solution**—is used for the colorimetric determination of ammonia, for it gives a yellow or brown coloration with ammonia or ammonium salts, and the intensity of the colour is proportional to the concentration of the ammonia present. The precipitate with Nessler's reagent is supposed to be mercuric hydroxyiodoamide: $\text{NH}_3 + 2\text{K}_2\text{HgI}_4 + 3\text{KOH} = 7\text{KI} + 2\text{H}_2\text{O} + \text{HgOH.NH.HgI}$. Several methods of preparing the reagent have been published in analytical works. A litre of Nessler's soln. is usually made by dissolving 60 grms. of potassium iodide in 100 c.c. of water and pouring this soln. on 25 grms. of mercuric chloride in a glazed porcelain mortar. The mixture is triturated until all is dissolved, and the soln. made up to 750 c.c. by the addition of water. Add 150 grms. of potassium hydroxide in sticks, and, when dissolved and cooled, gradually add sufficient of a sat. soln. of mercuric chloride to produce a slight permanent precipitate; dil. the soln. to a litre; and, after it has stood for some time to let the precipitate settle, decant off the clear liquid. The soln. is preserved in a bottle closed with a well-fitting rubber stopper. C. J. Tanret⁷ mixed 14.73 grms. of mercuric iodide with a soln. of 10 grms. of potassium iodide in 100 grms. of water, and added half its volume of a 1:3 soln. of sodium hydroxide. G. Egeling says that the presence of mercuric chloride raises the sensitiveness of the reagent, but sodium or potassium chloride has no result. L. L. de Koninck says that Nessler's reagent does not give a coloration or a precipitate with ammonia in absolute alcohol soln.; and the presence of alcohol in the aq. soln. hinders the reaction; the corresponding reaction with mercuric chloride resulting in the formation of mercuric chloroamide, $\text{Hg}(\text{NH}_2)\text{Cl}$, is not so much affected by the presence of alcohol. C. J. Tanret says that the ammonia reaction is not presented with methyl- or ethyl-amine, but K. W. Charitschkoff says that the amine hydrochlorides which are decomposed by aq. soln. of potassium iodide do give the reaction. L. Rosenthaler noted that organic compounds with primary or secondary hydroxyl groups are reduced, while those with tertiary hydroxyl groups are not reduced by J. Nessler's reagent. Various other organic compounds were found by J. Vamvakas, H. Ditz, E. Schulze, P. N. Raikow and C. Külümoff, etc., to reduce Nessler's reagent—gelatine, for instance, gives a lead-coloured emulsion; gum arabic also gives a grey precipitation which is prevented by tartaric acid.

H. Erdmann,⁸ and H. Grossmann obtained yellow prisms or needles by cooling a soln. of mercuric iodide in hot conc. rubidium iodide. H. Grossmann found them to be **rubidium triiodomercuriate**, RbHgI_3 , or RbI.HgI_2 . They are immediately decomposed by water with the separation of mercuric iodide; they dissolve without decomposition in alcohol; they are readily soluble in acetic acid, and behave chemically like the other alkali complexes with mercuric iodide. H. Grossmann made yellow lustrous four-sided plates of **rubidium tetraiodomercuriate**, 2RbI.HgI_2 , or Rb_2HgI_4 , from a soln. with the component salts in mol. proportions. The crystals become matt on exposure to air, and are easily soluble in water. H. Grossmann also obtained yellow plates of **rubidium dibromodiiodomercuriate**, $\text{Rb}_2\text{HgBr}_2\text{I}_2$, or 2RbBr.HgI_2 , from a soln. of mercuric iodide in rubidium bromide; the crystals are decomposed by water into their component salts; but they dissolve in alcohol without decomposition.

H. L. Wells⁹ prepared five caesium iodomercuriates, Cs_3HgI_5 ; Cs_2HgI_4 ; CsHgI_3 ; $\text{Cs}_2\text{Hg}_3\text{I}_8$; and CsHg_2I_5 . The corresponding chlorides and bromides of all except $\text{Cs}_2\text{Hg}_3\text{I}_8$ have been made, but no iodide or bromide corresponding with $\text{CsHg}_5\text{Cl}_{11}$. It is suggested by H. L. Wells that J. Holmes' ammonium octochlorotrimercuriate, $(\text{NH}_4)_2\text{Hg}_3\text{Cl}_8.4\text{H}_2\text{O}$, is the same type of compound as the salt $\text{Cs}_2\text{Hg}_3\text{I}_8$. According to H. L. Wells, the double iodides of mercury and caesium are all yellow. The colour of the salts CsHg_2I_5 and $\text{Cs}_2\text{Hg}_3\text{I}_8$, resembles normal potassium chromate, and the others become paler as the proportion of the caesium salt increases. All of them are decomposed by water, forming compounds containing more mercuric iodide than the original salt, or, at the limit,

mercuric iodide itself. It is therefore possible to take any one of these double salts, and, by recrystallizing from water and evaporating the resulting soln. to prepare the complete series of five double iodides, as well as the component simple iodides, without the use of any new material. It is noticeable that the iodides differ from the chlorides and bromides in not including a salt that can be recrystallized continually from water. This peculiarity is doubtless due to the comparative insolubility of mercuric iodide.

The salt **caesium pentaiodomercuriate**, Cs_3HgI_5 , or 3CsI.HgI_2 , is prepared like the corresponding chloride and bromide by crystallization—by cooling or spontaneous evaporation—from very conc. soln. of caesium iodide with but a small proportion of mercuric iodide. S. L. Penfield says the crystals are of diverse habit and belong to the rhombic bisphenoidal system with axial ratios $a:b:c = 0.5362:1:0.97975$; H. L. Wells gives the sp. gr. 4.605. When this salt is dissolved in a small quantity of hot water, **caesium tetraiodomercuriate**, Cs_2HgI_4 , or 2CsI.HgI_2 , crystallizes out on cooling, but with a larger proportion of water, everything remains in soln.; the same salt is produced under wide limits of conditions by cooling mixed soln. of the component salts with the caesium iodide in excess. The crystals have diverse habits, and belong to the monoclinic system; S. L. Penfield gives the axial ratios $a:b:c = 1.3155:1:0.9260$, and $\beta = 69^\circ 56'$. According to T. V. Barker, these crystals are isomorphous with ammonium selenate, $(\text{NH}_4)_2\text{SeO}_4$. The sp. gr. is 4.806. The salt is not dissolved or decomposed by alcohol; but it is decomposed by water giving either one of the salts containing mercuric iodide or mercuric iodide alone; all depends on the proportion of water used. The salt **caesium triiodomercuriate**, $\text{HgI}_2.\text{CsI}$, or CsHgI_3 , is formed only within narrow limits of concentration from soln. with a little more mercuric iodide or water than the two preceding salts. It is easiest to dissolve Cs_2HgI_4 in a little hot water, and on cooling the salt CsHgI_3 can be obtained, although it often happens that all three salts: $\text{Cs}_2\text{Hg}_3\text{I}_8$, CsHgI_3 , and Cs_2HgI_4 , are successively deposited from the soln.; and it is difficult to isolate CsHgI_3 in a pure state. The crystals form thin transparent plates; the crystal angles have not been measured. When the crystals are pressed on paper they rapidly become opaque, but H. L. Wells says "he was unable to determine whether this is caused by mol. rearrangement or loss of water of crystallization." An air-dried sample after press. on paper had no water of crystallization, whereas a sample quickly dried on paper had a composition in agreement with $\text{CsHgI}_3.\text{H}_2\text{O}$. The salt **caesium octoiodotrimercuriate**, $2\text{CsI}.3\text{HgI}_2$, or $\text{Cs}_2\text{Hg}_3\text{I}_8$, is formed under widely varying conditions; and is most conveniently made by cooling a soln. of Cs_2HgI_4 in the proper quantity of hot water, or by treating the same salt with not too much cold water. The monoclinic crystals vary considerably in habit, triangular plates and elongated prisms are common forms. S. L. Penfield gives the axial ratios $a:b:c = 0.3438:1:0.3544$, and $\beta = 71^\circ 55.5'$. The sp. gr. is 5.14. The salt dissolves in alcohol and is decomposed by water with the separation of mercuric iodide. If a hot aq. soln. of caesium iodide is sat. with mercuric iodide, **caesium pentaiododimercuriate**, CsHg_2I_5 , or $\text{CsI}.2\text{HgI}_2$, contaminated with more or less mercuric iodide or $\text{Cs}_2\text{Hg}_3\text{I}_8$ is separated out on cooling, but if dil. alcohol be used as solvent, this salt is readily formed in yellow prisms, which become red on standing in the aq. mother liquid; they are more stable in alcoholic soln., but when dried by pressing on paper they quickly become red without losing their crystal form. The decomposition products are probably HgI_2 and $\text{Cs}_3\text{Hg}_2\text{I}_8$. The crystal angles have not been measured.

H. L. Wells has made three double salts with bromine and iodine, viz. $\text{Cs}_3\text{HgBr}_3\text{I}_2$; $\text{CsHgBr}_2\text{I}_2$; and CsHgBrI_2 ; and one chloriodide, $\text{Cs}_2\text{HgCl}_2\text{I}_2$. When attempts were made to prepare bromoiodides with a larger proportion of iodide, there was an interchange of the halogen, and nearly pure double iodides were formed. **Caesium tribromodiiodomercuriate**, $\text{Cs}_3\text{HgBr}_3\text{I}_2$, or 3CsBr.HgI_2 , forms rhombic bisphenoidal crystals like those of Cs_3HgI_5 , with a pale yellow colour; **caesium dibromodiiodomercuriate**, $\text{Cs}_2\text{HgBr}_2\text{I}_2$, or 2CsBr.HgI_2 , forms

monoclinic crystals like those of Cs_2HgI_4 , with a faint tinge of yellow. This salt is possibly dimorphic, although only one form has yet been prepared. When the hot soln. cools, thin plates resembling those of the chloride, bromide, or chlorobromide are deposited first, and when the dilution is right, these crystals can be removed and stout monoclinic crystals like the iodide obtained. Only one form of **cæsium bromodiiodomercuriate**, $\text{HgI}_2 \cdot \text{CsBr}$, or $\text{CsHg} \cdot \text{BrI}_2$, has been prepared in pale yellow monoclinic crystals with axial ratios $a:b:c=0.978:1:0.743$, and $\beta=87^\circ 3'5''$. Only one form is known, although the three other salts of the 1:1 type are dimorphous. **Cæsium dichlorodiiodomercuriate**, $2\text{CsCl} \cdot \text{HgI}_2$, or $\text{Cs}_2\text{HgI}_2\text{Cl}_2$, is the only known chloroiodide; when attempts were made to prepare chloroiodides with more mercuric iodide, there was an interchange of halogens and a nearly pure iodide was formed. The salt $\text{Cs}_2\text{HgCl}_2\text{I}_2$ is formed only in very conc. soln. containing a great excess of the cæsium halide. It occurs in white slender radiating needles which instantly become red in contact with water owing to the formation of mercuric iodide. The crystals belong to the monoclinic system. The angles were not measured.

Three cuprous iodomercuriates have been reported with $\text{HgCl}_2:\text{CuI}$ in the mol. proportions 1:1, 1:2, and 1:4. P. Hess¹⁰ obtained what he regarded as **cuprous triiodomercuriate**, $\text{CuI} \cdot \text{HgI}_2$, or CuHgI_3 , by treating a soln. of the corresponding potassium salt, KHgI_3 , with cupric sulphate, decanting off the clear liquid, and washing the precipitate first with a dil. soln. of sodium thiosulphate, and later with distilled water, until iodine no longer appears in the washings. The precipitate was then dried over sulphuric acid in a desiccator. The madder-red product can be recrystallized from hydrochloric acid. E. Meusel, and E. Lenoble worked in a similar manner, but washed out the iodine with water only. S. M. Jørgensen also prepared a cuprous mercuric iodide, of unknown composition, by shaking mercury with a soln. of cupric polyiodide. L. Cramer made cuprous triiodomercuriate by the action of a dil. soln. of mercuric chloride, on an emulsion of cuprous iodide. The red powder is chocolate brown when heated to 70° , and the original colour is restored on cooling. The electrical conductivity of the solid was found by S. P. Thompson to be a maximum between 87.5° and 88.5° at which temp. the compound changes in colour from red to black. P. Hess found no chemical change occurs when heated to 100° , but at 150° mercuric iodide is evolved, and is completely expelled at a higher temp.; iodine is simultaneously given off, but the iodine is completely expelled only by repeatedly heating the powder with nitric acid.

M. Bellati and R. Romanese prepared **cuprous tetraiodomercuriate**, $2\text{CuI} \cdot \text{HgI}_2$, or Cu_2HgI_4 , from a mixture of cuprous and mercuric iodides in alcoholic soln.; and E. Caventou and J. E. Willm, by the action of cupric sulphate on a boiling soln. of potassium iodomercuriate. The sp. gr. of the product is 6.0956 at 0° ; the calculated value from the mixture law is 5.268, and there is accordingly a considerable contraction during the formation of the compound. M. Bellati, S. Lussana, and R. Romanese found that the colour changes from a bright red to a dark purple at 69.6° ; to a chocolate brown at 70.6° ; on cooling, the reverse changes occur at respectively 61.5° , 57.2° , and between 55.2° and 52.3° . The thermal expansion when θ is below 62° is $v=1+0.000078460\theta$; and when θ is above 72° , $v=1.006803+0.0000814728\theta$. There is an irregularity in the volume changes between 62° and 72° . The mean sp. ht. between θ_1 and θ_2 is $0.0532068+0.000041131(\theta_1+\theta_2)$; and the true sp. ht. at θ is $0.0532068+0.000082262\theta$. The heat of transformation at 70° is 2.3619, and at 60° , 2.3210 calcs. E. Caventou and J. E. Willm found that a cold soln. of potassium iodide slowly extracts mercuric iodide and leaves cuprous iodide while a hot soln. acts more quickly. W. Peters prepared the red diammino-compound by the action of ammonia gas on the dried salt; H. Ley and G. Wiegner, and W. Peters prepared green **cuprous hemiheptammino-tetraiodomercuriate**, $\text{Cu}_2\text{HgI}_4 \cdot 3\frac{1}{2}\text{NH}_3$, and brown **cuprous octammino-tetraiodomercuriate**, $\text{Cu}_2\text{HgI}_4 \cdot 8\text{NH}_3$, by the action of the gas on the dried salt.

M. Bellati and R. Romanese also report **cuprous hexaiodomercuriate**, $4\text{CuI} \cdot \text{HgI}_2$, or Cu_4HgI_6 .

In attempting to make cuprous iodomercuriates F. Anderlini obtained yellow crystals of two products which were too unstable for analysis, but he obtained compounds with $\text{HgI}_2 : \text{CuI} : \text{NH}_3$ in the approximate ratios 3 : 1 : 6, 2 : 1 : 3, 2 : 1 : 4, and 1 : 1 : 2. The compound **cuprous diammino-triiodomercuriate**, $\text{CuHgI}_3 \cdot 2\text{NH}_3$, was obtained by adding ammonium sulphite to a soln. of a copper salt, heating nearly to boiling, and adding a soln. of potassium mercuric iodide. Mercury separates out, and the soln. is kept at 50° until it is clear. The hot liquid is filtered, and on cooling brownish-yellow crystals separate out; these are washed with aq. alcohol and dried in a desiccator over a mixture of calcium oxide and potassium hydroxide—not calcium chloride. The crystals gradually redden on exposure to air; they melt with decomposition, below 100° ; they are decomposed by water and alcohol; they become blue, forming $\text{CuHgI}_4 \cdot 2\text{NH}_3$ by the action of ammonia in moist air; and they are soluble in a warm soln. of ammonium sulphite, but lose their colour and give off ammonia. F. Anderlini prepared **cuprous triammino-pentaïodo-dimercuriate**, $\text{CuHg}_2\text{I}_5 \cdot 3\text{NH}_3$, by dissolving the mercuric diammino-iodide, $\text{HgI}_2 \cdot 2\text{NH}_3$, in a soln. of ammonium sulphite, and adding an ammoniacal soln. of cupric iodide to the hot soln. When the blue liquid is kept at 60° – 70° , it gradually becomes yellow, and yellow crystals of the triammino-compound are deposited on cooling. The dry compound becomes red on exposure to air; it is decomposed by prolonged washing with water, and also by absolute alcohol but more slowly than by water. **Cuprous tetrammino-pentaïodo-dimercuriate**, $\text{CuHg}_2\text{I}_5 \cdot 4\text{NH}_3$, is obtained if in preparing the triammino-compound, the soln. are mixed cold, and warmed to 50° until the precipitate has redissolved. The bright yellowish-green crystals behave like the triammino-compound when exposed to air, to water, and to alcohol. F. Anderlini also reported a compound, **cuprous hexammino-hexaïodo-trimercuriate**, by a process resembling that for $\text{CuHg}_2\text{I}_5 \cdot 4\text{NH}_3$, but using strongly ammoniacal soln. The analyses do not show whether the green plates have the composition $\text{CuHg}_3\text{I}_6 \cdot 5\text{NH}_3$ or 6NH_3 . Two cupric ammino-iodomercuriates have been reported by S. M. Jörgensen and F. Anderlini, namely, 2 : 1 : 4 and 1 : 1 : 4. S. M. Jörgensen made **cupric tetrammino-tetraïodo-mercuriate**, $\text{HgI}_2 \cdot \text{CuI}_2 \cdot 4\text{NH}_3$, or $\text{CuHgI}_4 \cdot 4\text{NH}_3$, by the action of alcohol on a mixture of cupric tetrammino-tetraïodide, $\text{CuI}_4 \cdot 4\text{NH}_3$, and mercury for some hours at ordinary temp. The blue mass of crystals can be purified by recrystallization from hot ammoniacal alcohol. He also obtained the same compound by slowly cooling a hot soln. of cupric amminosulphate and potassium iodomercuriate, and washing the product, first with water and then with ammoniacal alcohol. F. Anderlini also prepared this compound by cooling a warm ammoniacal soln. of $\text{CuHg}_2\text{I}_6 \cdot 4\text{NH}_3$. The prismatic crystals of $\text{CuHgI}_4 \cdot 4\text{NH}_3$ are an intensely blue colour; they are gradually decomposed at 135° ; they are easily decomposed by water and by acids; when boiled with zinc and water iodine goes quantitatively into soln. and copper, mercury, and the excess of zinc remain; they dissolve in conc. soln. of neutral ammonium salts—chloride, bromide, sulphate, etc.—with the evolution of ammonia; and the soln. on cooling deposits green crystals of **cupric tetrammino-hexaïododimercuriate**, $\text{CuI}_2 \cdot 2\text{HgI}_2 \cdot 4\text{NH}_3$, or $\text{CuHg}_2\text{I}_6 \cdot 4\text{NH}_3$, which gives the original compound, $\text{CuI}_2 \cdot \text{HgI}_2 \cdot 2\text{NH}_3$, when treated with ammonia. S. M. Jörgensen previously prepared the compound $\text{CuI}_2 \cdot 2\text{HgI}_2 \cdot 4\text{NH}_3$ by shaking the blue soln. obtained by digesting at 30° cuprous iodide with an alcoholic soln. of iodine— $\text{CuI} + 9\text{I}$ —with mercury; the green liquid is decanted from the mercurous iodide, and warmed with alcoholic ammonia. The resulting blue liquid furnishes dark green crystals of the compound in question. S. M. Jörgensen made the same compound by mixing warm soln. of potassium iodomercuriate and cupric ammino sulphate; the crystals which separate on cooling were rapidly washed with water, and dried in darkness in vacuo over calcium chloride. The dark green crystals can be kept in sealed vessels, but in air they lose iodine and ammonia; they are

sensitive to light; they lose ammonia and mercuric iodide when heated to 135° ; by prolonged washing with water they form a mixture of cuprous and mercuric iodides, and also when treated with dil. acids; they are soluble in an alcoholic soln. of acetic acid; they behave like $\text{CuI}_2 \cdot \text{HgI}_2 \cdot 4\text{NH}_3$ towards zinc and water; and they form $\text{CuI}_2 \cdot \text{HgI}_2 \cdot 4\text{NH}_3$ when warmed with an excess of ammonia—some cupric iodide passes into soln.

H. W. B. Roozeboom and A. Steger¹¹ have studied the effect of temp. on mixtures of silver and mercuric iodides. When the liquid mixture solidifies, mixed crystals are formed in all proportions excepting for the gap between 5 and 20 mol. per cent. of silver iodide—the mixed crystals with less than 5 mol. per cent. of silver iodide are of the rhombic mercuric iodide type; and (β), those containing 20 to 100 mol. per cent. of silver iodide are of the regular silver iodide type. Liquid mixtures with between 5 and 20 mol. per cent. of silver iodide solidify at 242° into a mixture of the two types of mixed crystals; the gap is wider at lower temp. being from 2 to 35 mol. per cent. of silver iodide at 132.5° , as is illustrated in Fig. 33. The mixed crystals β , containing between 40 and 90 mol. per cent. of silver iodide, undergo a change, the maximum temp. of which is 158° , in a mixture with 66 mol. per cent. of silver iodide. Apparently the mixed crystals (β) are then changed into the compound $\text{HgI}_2 \cdot 2\text{AgI}$, and the maximum temp. of this change is strictly analogous to the maximum f.p. of a pure compound.

In the mixed crystals (β) containing either more mercuric iodide or more silver iodide than is required for the compound, the temp. of change is lowered, on the silver iodide side to the point 135° , 90 mol. per cent., on the mercuric iodide side to the point 118° , 40 mol. per cent., these two being analogous to eutectic points on freezing curves. On neither side of the maximum, however, is the pure compound formed; according to the side, there is an admixture of silver iodide or mercuric iodide. A further complication has been detected at low temp., inasmuch as the above-mentioned double salt undergoes a transformation at 50° – 45° , the colour changing from red to yellow. This has been discussed by R. E. Liesegang.

The evidence as to the formation of **silver tetraiodomercuriate**, $2\text{AgI} \cdot \text{HgI}_2$, or Ag_2HgI_4 , is not very definite. H. Wegelius and S. Kilpi prepared it by treating freshly precipitated well-washed silver chloride with potassium iodomercuriate; and E. Meusel, by treating a soln. of silver nitrate with potassium iodomercuriate. E. Meusel, however, said that the yellow precipitate he obtained is not a compound. L. Cramer prepared silver iodomercuriate as an emulsion by adding silver nitrate and potassium iodide to an emulsion of mercuric iodide in gum arabic. H. Rebenstorff crystallized the compound from a hot soln. of mercuric nitrate. M. Bellati and R. Romanese found the sp. gr. to be 5.9984 at 0° , when the value calculated from the law of mixtures is 6.038. E. Meusel and R. Böttger showed that when the yellow precipitate of mercuric and silver iodides is heated under water it becomes intensely red, and the yellow colour is restored on cooling; and they stated that

FIG. 33.—Equilibrium Diagram of Mixtures of Silver and Mercuric Iodides.

mechanical mixtures of the two insoluble iodides present a similar phenomenon. M. Bellati and R. Romanese studied the remarkable colour changes which occur when mixtures of mercuric and silver iodides are heated; the compound Ag_2HgI_4 was found to be canary-yellow at ordinary temp.; orange at 47.5° ; orange-red at 48.5° ; and bright red at a higher temp. The reversible colour change which occurs in the neighbourhood of 50° was supposed by A. E. Baur to be due to the decomposition of the complex salt, Ag_2HgI_4 , and not to dimorphism, because he observed no break in the e.m.f. curve up to 53° . H. Wegelius and S. Kilpi drew the opposite conclusion. They found that after adding silver chloride to the liquid, the canary-yellow precipitate which changes to a blood-red at 50° , gradually passes into the pale yellow colour of silver iodide as the proportion of silver chloride is increased. If so little silver chloride is present that the soln. after the formation of the canary-yellow precipitate still contains a considerable proportion of mercuric iodide, the transformation can be frequently repeated without forming solid silver iodide. H. W. B. Roozeboom places the transition point at 45° ; and H. Rebenstorff says that both modifications can exist in presence of one another between about 33° and 45° ; and he devised a colour thermoscope based on this transformation. According to M. Bellati and R. Romanese, the thermal expansion increases regularly up to 40° , so that the volume v , at the temp. θ° , is $v=1+0.00009537\theta$; between 45° and 50° , the volume changes are irregular owing to changes in the internal structure; and above 51° , the thermal expansion is again regular when $v=1.006165+0.000088102\theta$. They also find that the thermal expansion of the compound is greater than would be the case if it were a mechanical mixture. They give the mean sp. ht. between θ_1° and θ_2° as $0.035648+0.00057835(\theta_1+\theta_2)-0.0000052621(\theta_1^2+\theta_1\theta_2+\theta_2^2)$; the true sp. ht. at θ° , as $0.035648+0.0011567\theta-0.0000157863\theta^2$; the amount of heat required to raise the temp. from 0° to θ° as $1.58600+0.0613035\theta$; the sp. ht. at 51° as 0.06130 which they say is constant; and the heat of transformation at 50° as 2.0807 cals., and at 41° , 2.0283 cals. Alcohol gradually decomposes Ag_2HgI_4 into mercuric iodide.

M. Bellati and R. Romanese also cited evidence to show the formation of $\text{HgI}_2\cdot\text{AgI}$, and $\text{HgI}_2\cdot 2\text{AgI}$. They showed that the sp. gr., thermal expansion, sp. ht., and heat of transformation of $\text{HgI}_2\cdot 3\text{AgI}$ from the values for $\text{HgI}_2\cdot 2\text{AgI}$ and AgI agree with the assumption that $\text{HgI}_2\cdot 3\text{AgI}$ is a mixture. Similar evidence indicates that $\text{HgI}_2\cdot\text{AgI}$ and $\text{HgI}_2\cdot 2\text{AgI}$ are compounds. Thus, the sp. gr. of silver triiodomercuriate, AgHgI_3 , is 5.9302 at 0° , when the value calculated from the mixture law is 5.990 ; the thermal expansion is much greater than corresponds with the mixture law, being $v=1+0.000065689\theta$ for values of θ between 0° and 40° ; for values of θ over 50° , $v=1.003500+0.000084005\theta$; and there is a great irregularity between 40° and 52° as is the case with $\text{HgI}_2\cdot 2\text{AgI}$. The salt $\text{HgI}_2\cdot\text{AgI}$ shows similar colour changes to those presented by $\text{HgI}_2\cdot 2\text{AgI}$. The mean sp. ht. between θ_1 and θ_2 is $0.054404+0.00079681(\theta_1+\theta_2)$; the true sp. ht. at θ° is $0.054404+0.000159362\theta$; and the heat of transformation at 49° , 1.7525 , and at 41° , 1.7323 .

M. C. Lea prepared a compound or mixture with a composition approximating to silver dichlorodiodomercuriate, $2\text{AgCl}\cdot\text{HgI}_2$, by mixing moist and freshly precipitated silver chloride and mercuric iodide; and by the action of eq. quantities of potassium iodide, mercuric chloride, and silver nitrate. The yellow powder gradually reddens when heated above 38° , and the scarlet-red colour is a maximum at 60° ; the original colour is restored on cooling. The colour of the product is darkened in sunlight, and the original colour is restored in darkness. Consequently, M. C. Lea concludes that a compound is here in question.

According to P. F. G. Boullay,¹² when a hot aq. soln. of calcium iodide, sat. with mercuric iodide, is cooled, some mercuric iodide is deposited, and the mother liquid, on evaporation, furnishes crystals of what is thought to be calcium hexaiododimercuriate, $2\text{HgI}_2\cdot\text{CaI}_2$, or CaHg_2I_6 ; the crystals are decomposed by water, furnishing red mercuric iodide and a liquid which leaves a yellow mass on

evaporation. J. B. Berthemot also obtained yellow needles from the soln. obtained by boiling mercuric iodide with calcium oxide and alcohol. A. G. Duboin alternately dissolved calcium and mercuric iodides in water up to saturation when a soln. with the molar composition, $\text{CaI}_2 + 1.3\text{HgI}_2 + 12.3\text{H}_2\text{O}$, was produced—the sp. gr. was 2.89 at 15.9° . By cooling this soln., crystals of **octohydrated calcium tetraiodomercuriate**, $\text{CaI}_2 \cdot \text{HgI}_2 \cdot 8\text{H}_2\text{O}$, or $\text{CaHgI}_4 \cdot 8\text{H}_2\text{O}$, are formed; similar crystals were obtained by evaporating a soln. containing at 9.5° , 21.39–21.66 per cent. of water, 3.97 per cent. of calcium, 21.57–21.84 per cent. of mercury, and 52.8 per cent. of iodine. The yellow needle-like crystals have a sp. gr. 3.258 to 3.337 at 0° ; they are very deliquescent; they dissolve in water without decomposition; they also dissolve in many organic solvents without decomposition—e.g. methyl-, ethyl-, amyl-, butyl-, and isobutyl-alcohols; in allyl iodide, acetone, acetic acid, ethyl oxalate, aniline, they are sparingly soluble in nitrobenzene; and they are insoluble in chloroform, carbon tetrachloride, ethyl iodide, ethylene iodide, benzene, monochlorobenzene, and toluene. If mercuric iodide be dissolved in the mother liquid remaining after the separation of the above described crystals, and the soln. cooled to 0° , A. G. Duboin found that small crystals of **octohydrated calcium dodecaiodopentamercuriate**, $\text{CaI}_2 \cdot 5\text{HgI}_2 \cdot 8\text{H}_2\text{O}$, or $\text{CaHg}_5\text{I}_{12} \cdot 8\text{H}_2\text{O}$, which have a sp. gr. of 4.69 (0°), are formed. They are less deliquescent than those of $\text{HgI}_2 \cdot \text{CaI}_2 \cdot 8\text{H}_2\text{O}$; they are decomposed by water and by methyl-, ethyl-, and amyl-alcohols, by glycerol, aldehyde, acetone, and acetic acid, with the formation of red mercuric iodide; they are decomposed slowly by nitrobenzene and ethyl oxalate; and they are insoluble in monochlorobenzene, toluene, ethylene bromide, and chloroform. If the soln. just mentioned be further cooled below 0° , elongated prisms are also formed. These crystals have the composition **calcium tetradecaiodotetramercuriate**, $3\text{CaI}_2 \cdot 4\text{HgI}_2 \cdot 24\text{H}_2\text{O}$, and sp. gr. 3.56–3.66 at 0° ; they dissolve in water with the separation of mercuric iodide; they readily dissolve in methyl-, ethyl-, amyl-, butyl-, and isobutyl-alcohols, glycerol, ethyl acetate, methyl- and isobutyl propionates, allyl iodide, aldehyde, acetone, aniline, and ethyl oxalate; they are very sparingly soluble in nitrobenzene; and insoluble in monochlorobenzene, toluene, ethylene bromide, ethyl iodide, chloroform, carbon tetrachloride, etc.

According to P. F. G. Boullay, a soln. of strontium iodide, sat. hot with mercuric iodide, deposits part of the latter on cooling, and when the mother liquid is evaporated, it gives crystals of what was thought to be *strontium hexaiododimercuriate*, $\text{SrI}_2 \cdot 2\text{HgI}_2$, or SrHg_2I_6 , and which are decomposed by heat, or by treatment with water. J. B. Berthemot also made yellow crystals from the soln. obtained by boiling mercuric iodide with strontia water. The composition of these crystals has not been definitely established. A. G. Duboin alternately dissolved strontium and mercuric iodides in water at 16.5° until the soln. was saturated; the composition of the soln. was $\text{SrI}_2 + 1.24\text{HgI}_2 + 18.09\text{H}_2\text{O}$, and its sp. gr. 2.5; when strongly cooled, iridescent plates of **octohydrated strontium dodecaiodopentamercuriate**, $\text{SrI}_2 \cdot 5\text{HgI}_2 \cdot 8\text{H}_2\text{O}$, or $\text{SrHg}_5\text{I}_{12} \cdot 8\text{H}_2\text{O}$, and sp. gr. 4.66 (0°), separated out. The same salt was obtained in quantity by cooling a soln. of strontium iodide sat. with mercuric iodide at 70° . A second salt, **octohydrated strontium tetraiodomercuriate**, $\text{SrI}_2 \cdot \text{HgI}_2 \cdot 8\text{H}_2\text{O}$, or $\text{SrHgI}_4 \cdot 8\text{H}_2\text{O}$, was obtained in long prismatic crystals by the slow evaporation of a soln. with the composition: strontium, 7.85 per cent.; mercury, 21.22 per cent.; iodine, 50.44 per cent.; water, 20.49 per cent. The crystals have a sp. gr. 3.22 to 3.36 at 0° . The properties resemble those of the corresponding calcium salt.

P. F. G. Boullay prepared what was assumed to be *barium hexaiododimercuriate*, $\text{BaI}_2 \cdot 2\text{HgI}_2$, by a process analogous to that employed for the strontium salt. According to A. G. Duboin, a soln. saturated with both barium and mercuric iodides has the composition $\text{BaI}_2 + 1.33\text{HgI}_2 + 7.76\text{H}_2\text{O}$, and sp. gr. 2.76 at 23.5° . When this soln. is sat. at 70° with mercuric iodide, and cooled, it furnishes small crystals of **octohydrated barium dodecaiodopentamercuriate**, $\text{BaI}_2 \cdot 5\text{HgI}_2$.

$8\text{H}_2\text{O}$, or $\text{BaHg}_5\text{I}_{12}\cdot 8\text{H}_2\text{O}$, of sp. gr. 4.63 at 0° . This salt resembles the corresponding salts of strontium and calcium. A. G. Duboin evaporated a soln. containing $1.07\text{BaI}_2 + \text{HgI}_2 + 9.71\text{H}_2\text{O}$ in a desiccator over sulphuric acid, and obtained prismatic deliquescent crystals of **hexadecahydrated barium hexadeca-iodopentamercuriate**, $3\text{BaI}_2\cdot 5\text{HgI}_2\cdot 16\text{H}_2\text{O}$, or $\text{Ba}_3\text{Hg}_5\text{I}_{16}\cdot 16\text{H}_2\text{O}$, with a sp. gr. 4.06. Prismatic crystals of **hexadecahydrated barium decaiodotrimercuriate**, $2\text{BaI}_2\cdot 3\text{HgI}_2\cdot 16\text{H}_2\text{O}$, can be obtained by cooling a soln. containing $\text{BaI}_2 + 1.3\text{HgI}_2 + 10.4\text{H}_2\text{O}$. Similar crystals can also be obtained from the mother liquid remaining after the separation of $\text{BaI}_2\cdot \text{HgI}_2\cdot 8\text{H}_2\text{O}$. These crystals have a sp. gr. of 4 at 0° . If a soln. of the composition 12.45 per cent. barium, 22.53 per cent. mercury, 51.68 per cent. iodine, and 13.34 per cent. water, be evaporated in dry air at a summer heat, large flattened crystals of **pentahydrated barium tetraiodomercuriate**, $\text{HgI}_2\cdot \text{BaI}_2\cdot 5\text{H}_2\text{O}$, or $\text{BaHgI}_4\cdot 5\text{H}_2\text{O}$, and sp. gr. 4 at 0° , are obtained. H. Ley and G. Wiegner, and W. Peters prepared **barium octammino-tetraiodomercuriate**, $\text{BaHgI}_4\cdot 8\text{NH}_3$, from its constituents by the action of the gas on the dried salt. The absorption is rapid at 20° .

M. Herder proposed a soln. of barium mercuric iodide as a reagent for alkaloids; and C. Rohrbach prepared a soln. of barium and mercuric iodides—*Rohrbach's solution*—of sp. gr. 3.575 to 3.588, for separating heavy minerals.

100 grms. of barium iodide, and 130 grms. of mercuric iodide are mixed in a dry flask; 20 c.c. of water are added, and the mixture is continually agitated while being heated to 150° or 200° on an oil-bath. The soln. is then allowed to evaporate on a water-bath until a fragment of epidote floats thereon; the soln. is then allowed to cool, when a double salt is deposited. This is allowed to settle in a tall beaker, and the clear liquid decanted. Filtration is not recommended. The soln. is decomposed when diluted with water, and it is therefore diluted with a more dil. soln. Its properties are similar to Thoulet's soln. Rohrbach's soln. is not changed by carbon dioxide or by carbonates—e.g. calcite or chalk. The soln. boils at 145° . The refractive index of a soln. of sp. gr. 3.564 is 1.7755 for the *C*-line; 1.7932 for the *D*-line; 1.8265 for the *E*-line; and 1.8488 for the *F*-line; the dispersion $\mu_F - \mu_C$ is 0.0736, and $(\mu_F - \mu_C)/\mu_C$ is 0.0409. E. Clerici has measured the viscosity of the soln.

According to P. F. G. Boullay,¹³ a hot soln. of magnesium iodide sat. with mercuric iodide deposits a portion of the latter on cooling, and the mother liquid yields greenish-yellow needles on evaporation. These crystals are thought to be **magnesium hexaiododimercuriate**, $\text{MgI}_2\cdot 2\text{HgI}_2$. They are decomposed by water into red mercuric iodide, and, according to P. F. G. Boullay, a soln. of probably magnesium tetraiodomercuriate, $\text{HgI}_2\cdot \text{MgI}_2$. According to A. G. Duboin, a soln. of the composition $\text{MgI}_2 + 1.29 + 11.06\text{H}_2\text{O}$, and sp. gr. 2.92 at 17.8° , furnishes first a crop of crystals of **heptahydrated magnesium hexaiododimercuriate**, $\text{MgI}_2\cdot 2\text{HgI}_2\cdot 7\text{H}_2\text{O}$, or $\text{MgHg}_2\text{I}_6\cdot 7\text{H}_2\text{O}$, sp. gr. 3.8 (0°), and properties like the corresponding calcium salt; and then a crop of deliquescent octahedra of **enneahydrated magnesium tetraiodomercuriate**, $\text{MgI}_2\cdot \text{HgI}_2\cdot 9\text{H}_2\text{O}$, or $\text{MgHgI}_4\cdot 9\text{H}_2\text{O}$, sp. gr. 2.9. A. G. Duboin also reports crystals of $3\text{MgI}_2\cdot 5\text{HgI}_2\cdot x\text{H}_2\text{O}$, analogous with the corresponding barium salt. F. Calzolari and U. Tagliavini prepared crystals of a complex of $\text{HgI}_2\cdot \text{MgI}_2\cdot 10\text{H}_2\text{O}$ with hexamethylenetetramine.

According to P. A. von Bonsdorff, when an aq. soln. of zinc iodide, sat. with mercuric iodide, is evaporated over sulphuric acid in a desiccator, a first crop of crystals of mercuric iodide is followed by yellow deliquescent prisms of the double iodide; P. F. G. Boullay also reported that a hot aq. soln. of a mol of zinc iodide dissolves not quite two mols of mercuric iodide; the soln. deposits part of the last-named salt on cooling, and still more when diluted with water. According to A. G. Duboin, the crystals successively deposited from mixed soln. of mercuric and zinc iodides form a complete series of mixed crystals, and he believed that the crystals of **zinc tetraiodomercuriate**, $\text{ZnI}_2\cdot \text{HgI}_2$, previously described, are isomorphous mixtures and not definite compounds. A soln. saturated at 14.5° with both salts has the composition $\text{HgI}_2 + 1.87\text{ZnI}_2 + 16.33\text{H}_2\text{O}$, and sp. gr. 2.82. Similar remarks apply also to the crystals of **cadmium tetraiodomercuriate**,

$\text{CdI}_2 \cdot \text{HgI}_2$, and **cadmium octoiodotrimercuriate**, $\text{CdI}_2 \cdot 3\text{HgI}_2$, prepared as pale yellow crystals by J. B. Berthelot from the soln. obtained by triturating moist mercuric iodide with cadmium filings; and by F. W. Clarke and E. A. Kebler from a hot soln. of mercuric iodide in cadmium iodide. C. Sandonnini also obtained crystals containing all proportions of cadmium and mercuric iodides from fused mixtures of the component salts, Fig. 34. The transition temp. of mercuric iodide is lowered from 128° to 105° when 30 molar per cent. of cadmium iodide is present. F. Ephraim and P. Mosimann prepared pale yellow octahedra or cubes of **zinc mercuric tetramminotetraiodide**, $[\text{Zn}(\text{NH}_3)_4]\text{HgI}_4$. They also made **cadmium mercuric tetramminotetraiodide**, $[\text{Cd}(\text{NH}_3)_4]\text{HgI}_4 \cdot 4\text{H}_2\text{O}$, and **cadmium mercuric hexamminotetraiodide**, $[\text{Cd}(\text{NH}_3)_6]\text{HgI}_4 \cdot 6\text{H}_2\text{O}$, in conc. ammoniacal soln. These salts can also be regarded as zinc or cadmium aminotetraiodomercuriates. H. Ley and G. Wiegner, and W. Peters prepared $\text{CdHgI}_4 \cdot 6\text{NH}_3$ by exposing the product regarded as CdHgI_4 to the action of ammonia gas.

§ 27. The Sulphides of Mercury

Our knowledge of cinnabar probably goes as far back as that of mercury. Theophrastus, in his *Περὶ Λίθων*, written about 300 B.C., mentioned two kinds of *κιννάβαρ*—the natural and the fictitious. The former is analogous with cinnabar, the ore from which mercury is extracted; the latter appears to have been a powdered and levigated red sand obtained near Ephesus. Pliny, in his *Historia naturalis*, written at the beginning of our era, also speaks of the confusion between the mineral cinnabar, which he called *minium*, and *Indian cinnabar*, the dried juice or resin known as dragon's blood—*sanies draconis*—probably obtained from the calamus palm, or *Pterocarpus draco*. Pliny's contemporary, Dioscorides, also

called cinnabar *ἄμμιον*. Pliny's term minium is now reserved for red-lead. The subsequent history has been well outlined by H. Kopp, and M. Berthelot. The artificial preparation of red mercury sulphide—called *usifur*—was described by Geber in his *Summa perfectionis magisterii*, written about the thirteenth century; and, about the same time, Albertus Magnus, in his *Compositum et compositis*, showed that cinnabar, or *lapis rubeus*, is a compound of mercury and sulphur, because "when a mixture of mercury and sulphur is sublimed, a brilliant red powder of cinnabar is produced." This conclusion was repeated by many later writers¹—A. Libavius, J. Kunckel, G. E. Stahl, H. Boerhaave, J. J. Becher, N. Lemery, etc. J. S. Carl showed the identity of natural, artificial, and antimonial cinnabar, and stated that the composition was six parts of mercury and one of sulphur. Black mercuric sulphide was prepared near the beginning of the eighteenth century by W. Harris, and Turquet de Mayerne by triturating mercury and sulphur, and the product was variously called *æthiops mineralis*, *æthiops mercurialis*, *æthiops Turqueti* or *æthiops Harrisii*, *mineralis mohr*, *Quecksilbermohr*, or *æthiops empyros* or *apyros*, according as the sulphur employed was melted or not. In 1752, H. Ludolf prepared black mercuric sulphide by the action of a soln. of calcium sulphide on mercury or mercuric oxide; five years later, J. C. Jacobi used a soln. of alkali sulphide, and the product was called *pulvis hypnoticus*, or *narcoticus Krieli*, after D. S. C. Kriel, who recommended it as a medicine. In 1687, G. Schultz made cinnabar in the wet way by treating mercury with a soln. of ammonium sulphide, *spiritus fumans Boylei*; and a similar process was used by F. Hoffmann, and J. C. Wiegleb. A. Baumé showed that this sulphide soln. converts the black sulphide as well as mercury itself into cinnabar; and J. Senebier, that hydrogen sulphide acts slowly with the same result. The black and red forms of mercuric sulphide puzzled the early chemists. G. E. Stahl assumed that the black form contained more sulphur than the red one; P. J. Macquer, A. F. de Fourcroy, and L. N. Vauquelin assumed that the sulphur in the black form was less intimately associated with the mercury than in the red form; A. F. de Fourcroy also postulated that both compounds were sulphuretted mercury oxides, but that the red form was more oxidized than the black one; C. L. Berthollet assumed that cinnabar is a true sulphide, and that the black form is a hydrosulphide; C. F. Bucholz suggested the converse of Berthollet's hypothesis; J. B. Trommsdorff assumed that cinnabar is a sulphide, and that the black sulphide is a sulphuretted oxide. J. L. Proust, C. F. Bucholz, and J. M. Séguin showed the sulphides are free from oxygen; and in 1833 J. N. von Fuchs explained the difference by assuming that the black sulphide is amorphous, and that the red sulphide is crystalline.

The analyses of J. L. Proust, J. M. Séguin, N. J. B. G. Guibourt, N. G. Sefström, and O. L. Erdmann and R. F. Marchand correspond with the formula HgS. Cinnabar has been analyzed by A. Bealey, R. Varet, M. H. Klaproth, H. Müller, F. Pisani, and C. F. Rammelsberg; and metacinnabarite by J. Petersen, G. Cesaro, J. D. Whitney and G. E. Moore, F. A. Genth, W. H. Melville and W. Lindgren, R. Varet, O. Schumann, A. Schrauf, etc. The occurrence of metacinnabarite has also been discussed by G. Kroupa,² J. A. Krenner, W. H. Melville, and A. Schrauf. It was formerly believed that the ores of mercury were formed in nature by sublimation; and that the uniformity in the characteristics of most of the deposits points to a common origin. The presence of accessory minerals—calcite, opal, barite, etc.—is opposed to the sublimation hypothesis, and since hot springs and volcanic products are associated with most of the deposits, it is assumed that they have been formed by the agency of hot springs. At Almaden (Spain), Idria (Austria), and Nikitowka (Russia), the evidences of volcanic agents are not so marked, but since the characteristic mineral associations are the same, the latter theory still holds good. F. W. Clarke assumes that cinnabar was probably deposited from ascending soln. because such soln. are alkaline, and that metacinnabarite was deposited by descending soln. because of their acidity—the acid being derived from the oxidation of pyrites.

According to A. L. Orłowsky,³ with the exception of copper, mercury possesses a greater affinity for sulphur than any other metal; E. Schürmann, however, estimated the affinity of mercury for sulphur to be smaller than that of palladium, but greater than that for silver or copper; and O. Schumann said that the affinity of mercury for sulphur is smaller than that of barium, and nearly the same as that of the metal for oxygen. M. Berthelot observed no reaction between dry hydrogen sulphide and mercury at 100°. It is somewhat doubtful if all the reports of the preparation of **mercurous sulphide**, Hg_2S , can be substantiated, although it appears to be possible to prepare it at temp. below 0°.

According to H. V. Regnault, J. J. Berzelius, and W. T. Brande, mercurous sulphide is obtained by the action of hydrogen sulphide on a soln. of a mercurous salt, though N. J. B. G. Guibourt stated that the product is only a mixture of mercury and mercuric sulphide. C. Barfoed obtained similar results, and E. Weinschenk showed that a similar mixture is obtained by the action of compressed hydrogen sulphide on mercurous chloride. On the other hand, U. Antony and Q. Sestini probably obtained mercurous sulphide by the action of a mixture of hydrogen sulphide and carbon dioxide on mercurous chloride cooled by a freezing mixture below -10°. K. Brückner, and A. Violi also obtained what they regarded as mercurous sulphide by heating mercurous sulphate with sulphur; and C. Baskerville, by leaving mercury (10 grms.) in contact with 99.65 per cent. sulphuric acid (50 grms.) in a closed flask shut off from the direct action of sunlight. After about five years the black product was washed rapidly by decantation with much water, then with 95 per cent. alcohol, and dried at 110°.

According to U. Antony and Q. Sestini, the black or brownish-black powder is quite stable at -18°, but above 0°, it readily decomposes into mercury and mercuric sulphide. C. Baskerville found that when heated in a closed tube it becomes white—probably owing to oxidation—then yellow, and it finally melts to a dark orange liquid which on cooling forms white mercurous sulphate. W. Hittorf said that what was thought to be mercurous sulphide conducts an electric current like a metal, and W. Skey showed that it is more electropositive than silver towards a soln. of sodium chloride, and, when used as the negative pole of a cell, it is desulphurized. According to U. Antony and Q. Sestini, hydrogen chloride mixed with carbon dioxide rapidly converts mercurous sulphide into hydrogen sulphide and mercurous chloride; mercuric sulphide remains unchanged by this treatment. Dil. hydrochloric and dil. nitric acids do not act on mercurous sulphide below 0°, but more conc. nitric acid has a slight action; at a higher temp., these acids react as they would on a mixture of mercuric sulphide and mercury; fuming nitric acid rapidly oxidizes mercurous sulphide, forming mercuric nitrate and sulphur, which is partly oxidized to sulphuric acid. Ammonium sulphide or hydroxide, and alkali hydroxides have no action; sodium, or better, potassium sulphide, rapidly dissolves mercurous sulphide, forming a clear liquid which, as the temp. rises, becomes turbid owing to the separation of finely divided mercury, and the formation of mercuric sulphide.

There are three crystalline **mercuric sulphides**, HgS —the red form, $\alpha\text{-HgS}$, corresponding with cinnabar or vermilion; the black cubic form, corresponding with metacinnabarite, $\alpha'\text{-HgS}$; and a deep red hexagonal form, $\beta\text{-HgS}$, not found in nature. In addition, there is an amorphous or colloidal mercuric sulphide. Cinnabar is the stable form of mercuric sulphide at all temp. up to its sublimation point, about 580°; it is readily formed by the action of soluble alkali sulphides on the amorphous black sulphide—say, by heating the latter with a conc. soln. of ammonium sulphide in a sealed tube at 100°, when the colour becomes red in a short time, but the action is continued for about 24 hrs. to ensure a complete conversion. According to E. T. Allen and J. L. Crenshaw,⁴ black amorphous sulphide is always the first product of the action of alkali sulphides on mercuric salts, but cinnabar only is obtained when the precipitate is digested with alkaline soln.; no metacinnabarite was ever obtained under this condition. According to A. Christensen, when

mercuric salts—the oxalate, acetate, sulphate, chloride, iodide, etc.—are heated with an aq. soln. of ammonium monosulphide, the soln. become yellow owing to the partial liberation of sulphur, with the formation of ammonium polysulphide, and the precipitate is a mixture of mercury and mercuric sulphide. Yellow mercuric oxide also imparts the yellow colour to the soln. of ammonium sulphide, but the sulphur slowly returns to the solid, forming vermilion. Mercuric cyanide very quickly forms vermilion. Mercuric sulphide does not yield sulphur to ammonium sulphide soln., so that the liberation of sulphur occurs when the mercuric salt and ammonium sulphide interact. Sodium sulphide behaves like ammonium sulphide, but the separation of sulphur is less marked. B. S. Neuhausen studied the precipitation of mercuric sulphide from cyanide soln., and concluded that reactions at low conc. are between mols. or complex ions.

According to E. T. Allen and J. L. Crenshaw, the product of the action of soluble thiosulphates on mercuric salts depends on the ratio of the two salts in the soln., and also on the conc. The results are summarized in Fig. 35, with reference to 10 per cent. with about 2 per cent. of sodium chloride added, because the decomposition of sodium mercuric chloride proceeds more slowly than that of soln. of mercuric chloride and better crystals are produced. The line *AB* includes all soln. with the ratio $\text{HgCl}_2 : \text{Na}_2\text{S}_2\text{O}_3 = 3 : 2$, and soln. above that line contain more mercuric chloride; these soln. all furnish white *mercuric dichlorodisulphide*, $\text{HgCl}_2 \cdot 2\text{HgS}$; the reaction is symbolized: $3\text{HgCl}_2 + 2\text{Na}_2\text{S}_2\text{O}_3 + 2\text{H}_2\text{O} = \text{HgCl}_2 \cdot 2\text{HgS} + 4\text{NaCl} + 2\text{H}_2\text{SO}_4$. Soln. corresponding with the line *AC* contain $\text{HgCl}_2 : \text{Na}_2\text{S}_2\text{O}_3$ in the ratio 1 : 1, and soln. in the region between *AB* and *AC* furnish a mixture of mercuric thiochloride, and black mercuric sulphide: $\text{HgCl}_2 + \text{Na}_2\text{S}_2\text{O}_3 + \text{H}_2\text{O} = 2\text{NaCl} + \text{H}_2\text{SO}_4 + \text{HgS}$ (black). All soln. lying in the region between *AC* and *AD* precipitate at the beginning black mercuric sulphide, though later a red precipitate may be obtained. The line *AD* includes soln. in which the ratio $\text{HgCl}_2 : \text{Na}_2\text{S}_2\text{O}_3$ is as 1 : 4. Below *AD*, the principal reaction is $\text{HgCl}_2 + 4\text{Na}_2\text{S}_2\text{O}_3 = 2\text{NaCl} + 3\text{Na}_2\text{SO}_4 + 4\text{S} + \text{HgS}$. The mercuric sulphide precipitated at the beginning is a deep red modification which is not cinnabar; the precipitation of this compound continues until the dilution of the supernatant liquid has fallen to about one per cent. of mercuric chloride, when the black crystalline form appears. The reaction between sodium thiosulphate and sodium mercuric chloride renders the soln. slightly acid, a condition essential for the production of metacinnabarite. A. L. T. Mösveld also found that the metacinnabarite form is precipitated from faintly acid soln., and the cinnabar form from neutral or faintly alkaline soln.

Under the name *vermilion*, the red sulphide is employed as a pigment. The Chinese used it for colouring ink, paper, tapers, etc., and many temples in China are painted with the same colour; it is regarded by them as a lucky colour. Cinnabar is not used as a pigment because the impurities affect the colour. Vermilion is made by wet and dry processes. The dry processes depend on the preparation of the black sulphide, and its subsequent conversion into the red variety; and cinnabar is made by subliming a mixture of sulphur with mercury, mercury oxide, or mercury sulphate. According to H. Boerhaave, when 5–6 parts of mercury are added to one part of molten sulphur, and the mixture heated, with constant stirring until the sulphur thickens, the two elements unite with violent

FIG. 35.—The Action of Sodium Thiosulphate on Mercuric Chloride Solutions.

crackling, and the evolution of heat and light. The resulting mass is blackish-red, and appears to be a mixture of black and red mercuric sulphides with some uncombined sulphur and mercury. When this product is powdered, mixed with a little sulphur, and heated in a glass flask with a loose-fitting charcoal stopper, a sublimate of cinnabar is obtained; the more volatile free sulphur escapes, and the foreign metals, as sulphides, remain in the flask. If the upper part of the flask is too hot, some cinnabar is lost by volatilization. F. Pilz recommended washing the vermilion with a boiling soln. of potassium carbonate.

L. Gmelin described the old method of preparation formerly employed at Amsterdam and this is very like that just indicated. E. Mitscherlich described the old method employed at Idria, where the sulphur and mercury are agitated in rotating cylinders for some hours so as to furnish a brown powder. The mixture is heated in covered cast-iron cylindrical retorts with iron capitals; these are replaced by stoneware capitals with the beaks connected by a tube and receiver. The best vermilion collects in the capitals. This is removed and washed first with boiling sodium hydroxide, then water; the washed powder is then dried. Anonymous writers have described the Chinese method of preparation. This resembles in many respects that indicated above. The vermilion prepared by the above processes, said E. Wehrle, has a yellow tinge, and he claimed that if about one per cent. of antimony sulphide be added to the mixture of sulphur and mercury before sublimation, and the finely ground sublimate be boiled a number of times with a soln. of liver of sulphur, digested with hydrochloric acid, and afterwards washed and dried, it assumes the fine scarlet colour of the Chinese vermilion. No antimony can be detected in the final product.

C. Doelter made crystals of cinnabar by heating mercury with hydrogen sulphide in a sealed tube at 70° – 90° for several days; but if mercury be heated with an aq. soln. of hydrogen sulphide on a water-bath, a mixture of red and black sulphides is formed. According to F. Fouqué and A. M. Lévy, cinnabar was made by J. Durocher by the action of hydrogen sulphide on red-hot mercuric chloride, and by H. St. C. Deville and H. Debray, by heating the black precipitated sulphide with hydrochloric acid in a sealed tube at 100° . W. Spring obtained the red sulphide by strongly compressing a mixture of sulphur and mercury; and he also obtained red streaks by rubbing the black powder with an agate pestle and mortar.

The wet processes for making vermilion depend on the fact that alkali sulphides convert black into red mercuric sulphide. F. Hoffmann digested mercury with ammonium polysulphide, Boyle's spirit of sulphur, and obtained the red sulphide in a few days. A. Baumé obtained similar results with mercuric nitrate and Boyle's spirit of sulphur, but mercuric chloride did not work so well. J. L. Proust found that the black precipitated sulphide turns red slowly at ordinary temp., but rapidly when heated; the product is better with ammonium than with potassium polysulphide. L. J. Gautier-Bouchard used ammonium polysulphide. J. W. Döbereiner, and M. Firmenich used potassium polysulphide. A. Ditte attributed the action of alkali sulphides to the alternate formation and decomposition of double alkali mercuric sulphide; he said that $K_2S \cdot 5HgS$ is formed and decomposed at 45° with the deposition of the red crystalline sulphide, whilst the liberated alkali sulphide forms more double salt, and so the cycle continues anew. M. C. Mehu said that mercuric sulphide is insoluble in either sodium hydroxide or sulphide, but it is soluble in a mixture of the two; when the soln. is diluted, the black sulphide is deposited, but when carbon dioxide is passed through the soln., cinnabar is formed. L. L. de Koninck found that mercuric sulphide is very soluble in conc. soln. of the alkali and alkaline earth sulphides, but not in soln. of the hydrosulphides. When the soln. are rapidly diluted, black amorphous sulphide is precipitated, but when slowly diluted, red cinnabar is obtained. S. B. Christy, and J. A. Ippen heated amorphous mercuric sulphide in a sealed tube with alkaline soln. sat. with hydrogen sulphide and obtained cinnabar at 200° – 250° ; S. B. Christy said the reaction is retarded by the presence of carbon dioxide. C. Brunner compared the action of potassium, sodium, and ammonium polysulphides. G. S. C. Kirchhoff, and C. F. Bucholz employed a soln. of potassium hydroxide with sulphur in place of the polysulphide. A. Eibner used soln. of polysulphides of potassium, calcium, or

barium sat. with sulphur, and various compounds of mercury. V. Stanek obtained red mercuric sulphide by heating the precipitated sulphide with white ammonium sulphide in a sealed tube at 150° – 200° . It is difficult to remove all the alkali sulphide and sulphur from vermilion prepared by the alkali sulphide process, and these impurities are detrimental to the product. H. W. Picton and S. E. Linder recommended suspending the black sulphide in water, and passing in a stream of hydrogen sulphide until all is dissolved. Vermilion is precipitated when the soln. is heated in closed vessels to 160° – 170° for several hours. C. Brunner employed mercuric oxide, mercurous chloride, and basic mercuric sulphate; J. von Liebig, infusible white precipitate; U. Alvisi used mercuric ethyl sulphide, mercuric ethyl chlorosulphide, mercurous chloride, etc., with ammonium sulphide, or hydrogen sulphide with an acidic or alcoholic soln. of mercuric ethyl sulphide. E. Weinschenk prepared cinnabar by heating a soln. of mercuric chloride and ammonium thiocyanate in a sealed tube between 230° and 250° for 4–6 days. Both red and black sulphides were formed; the ammonium thiocyanate served to generate hydrogen sulphide. W. J. S. Grawitz dissolved mercuric oxide in a soln. of sodium thiosulphate, and precipitated the red sulphide by adding ammonium chloride, and warming the soln.; O. Hausamann heated a soln. of infusible white precipitate in a conc. soln. of sodium thiosulphate; F. J. Faktor similarly treated a soln. of mercuric chloride, F. Field a soln. of mercuric iodide, and H. Fleck a soln. of potassium mercuric thiocyanate, or sodium mercuric chloride in the same solvent. The reaction has also been studied by E. T. Allen and J. L. Crenshaw—*vide supra*. J. Schröder passed hydrogen sulphide into a soln. of mercuric bromide or iodide in pyridine, and obtained a red sulphide; with soln. of the chloride the precipitate was at first black and then red; and with very dil. soln. the thiochloride was formed. F. Bezold obtained the red sulphide by the action of an ammoniacal soln. of hydrogen sulphide on a soln. of mercuric iodide in methyl acetate—M. Hamers used ethyl acetate. E. Gerlach electrolyzed a soln. of 8 grms. ammonium citrate, 8 grms. of sodium nitrate, and 100 grms. of water in the presence of sulphuric acid. The deep red modification of mercuric sulphide, designated β -HgS, which is not cinnabar, was prepared by E. T. Allen and J. L. Crenshaw from soln. containing 10 per cent. of mercuric chloride and sodium thiosulphate with 2 per cent. of sodium chloride, provided the ratio $\text{HgCl}_2 : \text{Na}_2\text{S}_2\text{O}_3$ was between 1 : 1 and 1 : 4.

According to E. T. Allen and J. L. Crenshaw, when the red powder formed by the action of ammonium sulphide is sublimed in an evacuated glass tube, the sublimate is quite black. If the layer on the walls of the tube is very thin, or cooled with sufficient rapidity, it is entirely black, but in thick layers, the product is practically all coarsely crystallized cinnabar coated with a thin layer of black sulphide. It is not possible to say definitely if this coating is amorphous or if it is metacinnabarite. R. Kempf sublimed mercuric sulphide under 12 mm. press. at 400° and obtained metacinnabarite; W. Spring obtained it by subliming ordinary mercuric sulphide in an atm. of an indifferent gas—carbon dioxide, or nitrogen; H. Arctowsky, by heating a mixture of sulphur and mercuric chloride in an atm. of hydrogen; and E. T. Allen and J. L. Crenshaw, by boiling 6 grms. of mercuric chloride, 60 grms. of sodium chloride, and 12 grms. of sodium thiosulphate in 4 litres of water and 10 c.c. of 30 per cent. sulphuric acid, washing the precipitate with alcohol and ether, then with carbon disulphide, and finally drying in vacuo at 250° . J. M. Séguin converted cinnabar into the black sulphide by heating it out of contact with air; if the temp. is too high, cinnabar sublimes, and if the black colour is to be retained on cooling, the cinnabar must be heated until it begins to volatilize, and immediately the sublimation of the sulphide began, J. N. von Fuchs plunged the tube of mercuric sulphide into cold water. The red sulphide blackens when heated to 320° , and the red colour is restored by fast or slow cooling; if heated to 410° , W. Spring found that the black colour remains on cooling; and he converted some red into black sulphide by trituration. M. Roloff converted red into black sulphide by exposure to light, and K. Heumann said that the transformation

is dependent on the presence of moisture; it does not occur when the red sulphide is under acids, but under alkaline soln. it proceeds faster than under water.

Black amorphous sulphide is produced with the development of heat when the two elements are triturated at ordinary temp. If other than eq. proportions are used, the excess of either element remains in a free state, and C. G. Mitscherlich removed the excess of sulphur with carbon disulphide, and M. af Rosenschöld, the excess of mercury with dil. nitric acid. T. W. C. Martius agitated the mixture by fixing the containing bottle to the beam of a sawmill. F. D. Lichtenberg warmed the mortar in which the trituration was made; if heated too strongly, some red sulphide was formed. A. Monheim triturated equal parts of sugar, sulphur, and mercury with a little water and afterwards washed out the sugar; P. L. Geiger likewise triturated a mixture of sulphur and mercury with about 10 per cent. of ammonium sulphide, and P. R. Destouches used potassium sulphide. The soluble sulphides were afterwards removed by washing. R. von Schrötter found that when a piece of sulphur is placed in a barometric vacuum, in darkness, the black sulphide is formed in a few days; in light, some red sulphide is also formed. J. Dewar noted the formation of the black sulphide at the temp. of liquid air. When mercury is agitated with an excess of an aq. soln. of ammonium or alkali polysulphide, the black sulphide is formed, and if sulphur is added, the polysulphide is reformed, and the conversion of the mercury is completed.

According to C. Barfoed, mercurous salts with hydrogen sulphide, or colourless ammonium sulphide, give a mixture of black amorphous sulphide and mercury. L. Freundt made the black sulphide by digesting a soln. of mercurous nitrate with washed flowers of sulphur, but G. Vortmann and C. Padberg found that but little sulphide is formed when mercurous sulphide is boiled with sulphur and water. A. Baumé found black mercuric sulphide is precipitated by hydrogen sulphide or alkali hydrosulphides from soln. of mercuric salts—E. Weinschenk stated that the precipitate is the cinnabar not the metacinnabarite modification. Alkali chlorides were found by E. Rupp to favour the coagulation of the precipitate. U. Antony and Q. Sestini mixed soln. of hydrogen sulphide and an aq. suspension of mercurous chloride or acetate. N. Tarugi mixed soln. of mercuric thioacetate and ammonium sulphide. J. H. Thwaites found zinc sulphide precipitated mercuric sulphide from cold soln. of mercuric salts. J. Schröder found dry pyridine soln. of mercuric chloride or cyanide gave the black sulphide when treated with dry hydrogen sulphide, and the red sulphide with analogous soln. of mercuric bromide or iodide. F. J. Faktor obtained the black sulphide by the action of dry sodium thiosulphate on mercuric chloride; when cinnabar is sublimed from sodium thiosulphate, the black sulphide is formed, and the product is reddened by trituration.

According to F. Cornu,⁵ native black amorphous mercuric sulphide is colloidal. A. Lottermoser prepared **colloidal mercuric sulphide** by the action of hydrogen sulphide on a finely divided suspension of mercuric oxide; he also dialyzed the deep soln. obtained by passing hydrogen sulphide into a soln. of mercuric cyanide. H. R. Procter and R. A. S. Jones precipitated mercuric sulphide from a soln. of mercuric salts in the presence of certain organic acids—formic or citric acid. C. Winssinger, and H. W. Picton and S. E. Linder suspended in water the precipitate produced by passing hydrogen sulphide into a soln. of mercuric chloride, and passed hydrogen sulphide in excess through the liquid. It was suggested by H. W. Picton and S. E. Linder that the products are *mercuric hydrosulphides*, $\text{HgS} \cdot n\text{H}_2\text{S}$. J. Lefort and P. Thibault treated a soln. of gum arabic and mercuric chloride with sodium sulphide. J. Hausmann allowed a soln. of mercurous nitrate to diffuse into a 5 per cent. gelatine soln. of ammonium sulphide. W. Leuze treated a soln. of sodium protalbate or lysalbate with one of mercuric chloride. A. Pieroni added a soln. of hydrogen sulphide in pyridine to a soln. of mercuric acetate in the same solvent. E. W. Lewis and H. Waumsley treated mercury with carbon disulphide containing about 0.5 per cent. of caoutchouc, and 10 per cent. of benzene.

The physical properties of mercuric sulphide.—According to E. T. Allen and J. L. Crenshaw,⁶ the colour of the mercuric sulphide powder formed by ammonium sulphide is a lighter scarlet-red than that prepared by using an excess of alkali sulphide. The difference is solely one of subdivision, the darker product consists of crystals easily recognized by the naked eye, and the colour of these, when ground in a mortar, is scarcely distinguishable from that of the powder made by using ammonium sulphide. The colour of cinnabar varies from scarlet-red to brownish-red and lead-grey. B. F. Hill has described ruby-red crystals of cinnabar, and P. W. Jeremejeff, a variety cochineal red about the edges, and lead-grey in the thicker parts. When heated, vermilion-red acquires a brownish tinge, and it becomes quite brown at 250°, and black at a higher temp. If the temp. has not been up to the point of volatilization—400°, according to E. T. Allen and J. L. Crenshaw—the scarlet colour is restored on cooling; otherwise the colour remains black, as previously indicated. The temp. at which cinnabar becomes permanently black is not an inversion point. E. T. Allen and J. L. Crenshaw's hexagonal form, β -HgS, has rather a deeper red colour than ordinary cinnabar, but it is not distinguishable from cinnabar by colour alone. Metacinnabarite is black, with a reddish or brownish streak. The amorphous sulphide is black. The colloidal soln. are black, or if dil., brown.

Metacinnabarite forms hexacistetrahedral crystals belonging to the cubic system. They were studied by A. Schrauf,⁷ W. H. Melville, M. François and C. Lormand, H. Arctowsky, G. E. Moore, W. Spring, E. T. Allen and J. L. Crenshaw, etc. The crystals of the artificial black sulphide, α' -HgS, have not been definitely identified with the native mineral on account of the minute size and poor development. The crystals show typically six spindle-shaped rays apparently equal, and meeting at right angles—so that they indicate a skeletal growth parallel to the axes of the cube. J. B. L. Romé de l'Isle supposed the crystal form of cinnabar to be probably tetrahedral, and R. J. Haiüy showed them to be hexagonal. In a *Monographie der Krystallformen des Zinnober*, A. Schabus reported the axial ratio to be $a:c = 1:1.1453$, and $\alpha = 92^\circ 30'$. Artificial cinnabar forms red hexagonal prisms or plates. Different forms were investigated by A. des Cloizeaux, O. Mügge, A. Schmidt, H. Traube, E. T. Allen and J. L. Crenshaw, etc. E. T. Allen and J. L. Crenshaw's modification, β -HgS, is prismatic in habit, and has been obtained in crystals not exceeding 0.003 mm. in width, and 0.03 mm. in length; the crystals taper towards the ends, and have no distinct faces. They are generally aggregated in stellate groups. F. Haber found by X-radiograms that the amorphous precipitate of mercuric sulphide has a great tendency to assume the crystalline state. C. Mauguin was unable to establish the character of the space-lattice from his observations on the X-radiograms of cinnabar.

According to R. Boyle, the **specific gravity** of different samples of cinnabar ranges from 7.57 to 8.1. C. J. B. Karsten gave 8.0602 for the sp. gr. of sublimed cinnabar; P. F. G. Boullay gave 8.124; E. T. Allen and J. L. Crenshaw gave 8.176 for the sp. gr. of purified red mercuric sulphide at 25°/4°; and W. Spring gave for the sp. gr. and **specific volume** of precipitated red mercuric sulphide:

	21.6°	23.5°	34.4°	34.6°	56.6°	77.7°
Sp. gr. . . .	8.1289	8.1246	8.1004	8.1016	8.0830	8.0886
Sp. vol. . . .	123.018	123.082	123.450	123.432	123.675	123.629

and of sublimed red mercuric sulphide:

	15.8°	18.0°	34.6°	56.7°	77.5°	77.7°
Sp. gr. . . .	8.1587	8.1464	8.1181	8.0906	8.0979	8.0978
Sp. vol. . . .	122.569	122.754	123.182	123.588	123.488	123.490

E. T. Allen and J. L. Crenshaw gave 7.20 for the sp. gr. of β -HgS at 25°/4°. G. E. Moore gave 7.701–7.748 for the sp. gr. of metacinnabarite; W. H. Melville, 7.095–7.142; A. Schrauf, 7.766; S. L. Penfield, 7.81; and E. T. Allen and

J. L. Crenshaw, 7·60, at 25°/4°. W. Spring gave 124·385 for the sp. vol. of metacinnabarite. W. Orloff computed the **molecular volume** of cinnabar to be 28·75; and metacinnabarite, 29·99. G. E. Moore gave 7·552 for the sp. gr. of amorphous black mercuric sulphide; and W. Spring, 7·5543 at 20°. The latter also gave for the sp. gr. and sp. vol. of the amorphous sulphide:

	18°	23°	35°	56°	56°	77°	77°
Sp. gr.	7·6242	7·6047	7·5697	7·5500	7·5494	7·5578	7·5610
Sp. vol.	131·160	131·496	132·106	132·452	132·454	132·313	132·225

The **hardness** of native cinnabar is 2 to 3·5 on Mohs' scale; and G. E. Moore gave 3·3 for that of metacinnabarite. A. Ries and L. Zimmermann have discussed this subject.

The **coefficient of thermal expansion** of cinnabar, according to H. Fizeau,⁸ is $\alpha=0\cdot00002147$ parallel to the principal axis, and $0\cdot00001791$ perpendicular to that axis when the temp. is 40°; the temp. coeff. of the former is $da/d\theta=0\cdot07151$, and of the latter, $0\cdot07063$. According to E. Jannetaz, the sq. root of the ratio of **thermal conductivity** of cinnabar in the direction of the principal axis to that in the direction of the base is 0·85; L. Godard also measured the diffusion of heat in cinnabar. H. Kopp gave 0·0517 for the **specific heat** of cinnabar between 12° and 51°; H. V. Regnault, 0·0512 between 14° and 98°; F. Streintz, 0·0548; A. A. de la Rive and A. Marcet gave 0·0597; A. Sella, 0·0529; and W. Spring gave:

	25°-30°	35°-40°	45°-50°	55°-60°	65°-70°	75°-80°
Sp. ht.	0·0749	0·0871	0·0934	0·0985	0·1074	0·1270

A. S. Russell gave 0·0391 between -189° and -79°; 0·0488 from -74° to 0°; and 0·0515 from 2° to 49°. H. V. Regnault gave 0·0512 for the sp. ht. of the black sulphide between 14° and 98°; F. Streintz gave 0·1026; and W. Spring:

	25°-30°	35°-40°	45°-50°	55°-60°	65°-70°	75°-80°
Sp. ht.	0·0835	0·0967	0·1102	0·1103	0·1206	0·1433

M. Goldstein gave 5·9 for the **molecular heat** of cinnabar. E. Tiede and A. Schleele found that although mercuric sulphide sublimes without melting when heated under atm. press., the **melting point** is 1450° under a press. of 120 atm., furnishing a steel-grey matt solid which becomes red when rubbed. Mercuric sulphide volatilizes without melting at atm. press. According to E. T. Allen and J. L. Crenshaw, the **vapour pressure** reaches one atm. at 580°. and the compound is stable over the whole temp. range up to the volatilization point. The other two forms are monotropic, because at 100°, both α' -HgS and β -HgS are changed into cinnabar with a soln. of ammonium sulphide, while at 200°, the same change occurs slowly in sealed tubes with 30 per cent. sulphuric acid; and at 400°, 450°, 500°, and 550°, both are transformed into cinnabar when heated alone in evacuated glass tubes. C. Zenghelis stated that cinnabar volatilizes slightly at ordinary temp. in vacuo. G. F. Hildebrandt stated that it sublimes in closed vessels without decomposition and without residue. According to F. Damm and F. Krafft, volatilization begins at 400° when cinnabar is exposed to the cathode light in vacuo. W. Biltz gave the volatilization temp. of cinnabar as $446^\circ \pm 10^\circ$, and A. de Gramont found that it volatilizes rapidly in the electric arc. A. Schrauf stated that metacinnabarite begins to volatilize in air at 240°. E. Mitscherlich found the **vapour density** to be between 5·51 and 5·99; V. and C. Meyer gave 5·39—calculated for a mixture of Hg and S₂, 5·34. A. Schrauf estimated the minimum mol. wt. to be Hg₃S₃; and A. Scott calculated the mol. wt. to be 151·8 at high temp.

J. Thomsen⁹ found the **heat of formation** to be (Hg, S)=16·89 Cals.; and $\text{Hg}(\text{NO}_3)_2\text{aq.} + \text{H}_2\text{Saq.} = \text{HgS} + 2\text{HNO}_3 + 38\cdot87$ Cals.; and M. Berthelot gave for (Hg, S)_{black precipitate} 10·6 Cals. The black amorphous sulphide, according to R. Varet, is transformed into the red amorphous sulphide with the evolution of 0·24 Cal.,

and into the red crystalline form with 0.30 Cal.; so that the transformation of red amorphous into red crystalline is attended by the evolution of 0.06 Cal.

A. des Cloizeaux¹⁰ found the **refractive index** of cinnabar for red light to be $\omega=2.854$, and $\epsilon=3.201$; and for the Li-ray, $\omega=2.816$, and $\epsilon=3.142$. K. Zimanyi also measured the refractive index of Almaden cinnabar. H. E. Merwin and co-workers found $\omega=2.81$, and $\epsilon=3.14$ for the Li-ray; for the hexagonal β' -HgS, $\omega=2.58$, and $\epsilon=2.85$, for a ray $\lambda=650\mu\mu$ and the dispersion $\epsilon-\omega=0.24$. The crystals of mercuric sulphide have a high refractive index. Cinnabar and metacinnabarite have a strong positive double refraction, and they are optically uniaxial. The **circular polarization** of cinnabar was studied by A. des Cloizeaux, G. Wyruboff, G. Tschermak, and W. H. Melville and W. Lindgren. The **dispersion** of cinnabar crystals was measured by H. Rose, and found to deviate from Drude's and Ketteler's formulæ. E. L. Nichols and B. W. Snow measured the **reflecting power** of cinnabar for rays of different wave-length between 25° and 220° . A. de Gramont found that the **spark spectrum** of cinnabar showed the lines 579, 577, 546, 436, and $404\mu\mu$, as well as many sulphur lines. K. Heumann found that cinnabar exhibits **thermoluminescence** glowing with a feeble white glow—J. Calafaty Leon said a blue glow—when heated. S. M. Losanitsch found specimens of cinnabar from Alva and Bare (Serbia) and Idria (Austria) have a smaller **radioactivity** than pitchblende. Other mercury minerals examined were inactive. The barytes which accompanies the active cinnabar is inactive, from which it is concluded that radium is absent and that the activity is due to a "radio-mercury." The activity is completely removed by igniting the mineral. According to A. Verneuil, the presence of $\frac{1}{1000}$ th part of mercuric sulphide in calcium sulphide changes the colour but not the intensity of the phosphorescence. B. Gudden and R. Pohl, and H. Rose found cinnabar showed a **photoelectric effect**; and H. Rose studied the effect of temp. on the refraction of light by cinnabar, and also the absorption spectrum of that compound. The coagulation of colloidal mercury sulphide in light was observed by P. B. Ganguly and N. R. Dhar.

A. de Gramont,¹¹ and G. Cesaro found that cinnabar has a feeble **electrical conductivity**. The conductivity was found by J. Gibson to increase on exposure to light. R. G. van Name said the conductivity of red and black mercuric sulphides amounts to 0.01 to 0.02×10^{-6} . According to G. Karsten, F. Beyerinck, and G. Cesaro, metacinnabarite is a good conductor. Black mercuric sulphide was found by F. Streintz to conduct well when pressed into rods under a press. of 10,000–13,000 atm. The resistance falls from 41 ohms at 16° to 11.1 ohms at 100° and rises to about 25 ohms at 140° . W. Mönch made observations on this subject. C. H. Hall found colloidal mercuric sulphide suspended in oil is not precipitated by alternating or direct currents of voltages 10^4 to 2×10^5 .

The chemical properties of mercuric sulphide.—Black mercuric sulphide reacts chemically much the same as the red sulphide, only more vigorously. K. Heumann¹² found that red mercuric sulphide prepared by digestion with ammonium sulphide is decomposed more rapidly by exposure to *light* than is the case with that prepared by sublimation. In water-colour painting, said A. H. Church, most vermilion are found to be changed on exposure, the solar rays gradually converting the red into the black sulphide without producing any chemical alteration. This change occurs even in the absence of air and moisture. Impure air, *per se*, even if hydrogen sulphide be present, does not alter vermilion. W. D. Bancroft added that the varnish on a picture cuts off the ultra-violet light to a very great extent, and protects the picture in this way, in addition to keeping out moisture and gases. Red mercuric sulphide was found by K. Heumann to be blackened when exposed to sunlight under conc. aq. ammonia, but there is no separation of sulphur or mercury. Commercial sublimed vermilion is superficially blackened in a few minutes when kept under conc. aq. soln. of ammonia, or alkali hydroxide, and with vermilion prepared in the wet way, the blackening occurs in a couple of seconds. When preserved for a long time under water acidified with nitric

acid, vermilion showed no signs of blackening; if the vermilion prepared in the wet way contains traces of mercurous nitrate, it is blackened in darkness when confined under a soln. of ammonia or sodium hydroxide; boiling the product with dil. nitric acid restores the red colour. W. Ramsay and M. W. Travers found that native cinnabar contains occluded carbon monoxide.

H. Pélabon found that **hydrogen** reacts slowly with crystalline cinnabar at 280° ; and in a closed vessel, equilibrium is attained in about 90 hrs. at 360° when about 78.67 per cent. of hydrogen sulphide is present; at 440° , there is 85.29 per cent.; and at 540° , 92.10 per cent. The ratio $H_2 : H_2S$ is dependent on the initial press., and is smaller in the presence of an excess of mercury. G. Pollacci found that the moist precipitated sulphide is oxidized more quickly than cupric sulphide. According to G. F. Hildebrandt, when cinnabar is heated in air, it burns with a blue flame, forming sulphur dioxide and the metal. K. Friedrich stated that no decrepitation occurs when cinnabar is heated in air or **oxygen**; sulphur dioxide begins to be formed between 230° and 297° —depending on the grain-size; fumes begin to appear between 348° and 430° ; and the mass ignites between 380° and 450° . F. Janda has studied the changes which occur during the roasting of cinnabar for the metal—*q.v.* A. Mailfert found **ozone** reacts slowly with mercuric sulphide, converting it into sulphate. H. V. Regnault observed that at a red heat **water** vapour furnishes hydrogen sulphide, a black sublimate, much metallic mercury, but no mercury oxide. G. A. Binder found that distilled water acting on cinnabar for 5 weeks at 90° dissolves traces of the mineral. According to G. Bodländer, mercuric sulphide is less soluble in water than is silver or cuprous sulphide. O. Weigel found that a litre of water dissolved 0.054×10^{-6} mol of precipitated mercuric sulphide; and J. Knox that a litre of water at 24° dissolves 1.7×10^{-27} mol, and the solute is completely dissociated. P. de Clermont and M. Frommel found that the precipitated sulphide is not decomposed by water at 100° . T. M. Broderick found that cinnabar is dissolved by natural chloride-waters but not by sulphide-waters. W. Spring believed that **mercuric oxytrisulphide**, $HgO \cdot 3HgS$, is formed by boiling the sulphato-sulphide, $HgS \cdot 3HgSO_4$, with water; but T. Poleck doubted the existence of the oxysulphide. In all reactions examined by T. Poleck and C. Goercki a mixture of the sulphide and oxide was formed, and the latter was removable by dil. hydrochloric, sulphuric, or acetic acid, by formamide, or by digestion with a soln. of potassium iodide at 140° .

According to F. Field,¹³ cinnabar burns in **chlorine** with incandescence, forming sulphur chloride, S_2Cl_2 , and mercuric chloride; when boiled with a mixture which develops chlorine—say, manganese dioxide or antimonious or arsenious oxide and hydrochloric acid—mercuric chloride and sulphur are formed; and when treated with **aqua regia**, it dissolves quantitatively as mercuric chloride—only a little sulphuric acid is formed. G. F. Hildebrandt, and J. B. Hannay also noted the solubility of cinnabar in aqua regia; A. Schrauf also found that metacinnabarite dissolves in cold aqua regia with the separation of flocculent sulphur. E. Schäfer found cinnabar to be slowly decomposed by **bromine** at ordinary temp. and rapidly when heated, while E. Filhol and J. Melliès stated that **iodine** alone or in ethereal, chloroform, or aq. soln. acts on mercuric sulphide alone, or suspended in water or alcohol, forming mercuric iodide; and R. Wagner found that a soln. of iodine in potassium iodide decomposes cinnabar: $HgS + 2KI + I_2 = S + K_2HgI_4$. B. S. Neuhausen studied the action of iodine on mercuric sulphide. According to M. Berthelot, hydrogen chloride decomposes cinnabar. G. F. Hildebrandt said that **hydrochloric acid** has no action. U. Antony and L. Niccoli also found that hot acid of medium conc. has no action on mercuric sulphide; but, according to S. M. Jörgensen, the conc. boiling acid gives a little hydrogen sulphide, and, when the soln. cools, yellow mercuric thiochloride is deposited. M. Berthelot said that mercuric sulphide is decomposed by fuming hydrochloric acid. According to W. B. Rising and V. Lehner, mercuric sulphide readily dissolves in boiling 20 per cent. **hydrobromic acid** furnishing hydrogen sulphide and mercuric bromide; and,

according to S. M. Jørgensen, the conc. acid attacks mercuric sulphide in the cold, and when warmed a colourless soln. is quickly formed. A. Kekulé stated that conc. **hydriodic acid** dissolves mercuric sulphide in the cold; but the dil. acid required to be heated.

Salts of the hypothetical acid $\text{H}_2\text{S}.\text{HgS}$, or H_2HgS_2 , are known. H. W. Picton and S. E. Linder¹⁴ found that when **hydrogen sulphide** is passed into water containing mercuric sulphide in suspension, some of the latter is dissolved—10 grms. per litre—this is probably colloidal, since, according to J. Knox, the conc. of the complex which is formed is of the order 10^{-14} mol per litre. J. N. Mukherjee and N. N. Sen found that a soln. of hydrogen sulphide stabilizes mercuric sulphide sol against coagulation and an increased stability occurs with ammonium and potassium chlorides, and a decrease with barium and strontium chlorides. The stability of the sol is also increased by dilution irrespective of the nature of the electrolyte. The data which have been published on the solubility of mercuric sulphide in soln. of **alkali sulphides** and **alkali hydrosulphides** are contradictory. M. C. Mehu stated that mercuric sulphide is insoluble in either sodium hydroxide or sodium sulphide, but that it is soluble in a mixture of the two; however, according to L. L. de Koninck, mercuric sulphide is very soluble in conc. soln. of the alkali sulphides—even in the absence of alkali hydroxides—and in those of the alkaline earths, but is not soluble in soln. of the hydrosulphides or in ammonium sulphide, $(\text{NH}_4)_2\text{S}$. G. F. Becker found that this statement is true only for cold soln., for when heated with a soln. of sodium hydrosulphide, mercuric sulphide dissolves; it is also soluble in soln. of sodium sulphide and in mixtures of the two. Mercuric sulphide is completely soluble in a mixed soln. of sodium hydroxide and sulphide when the ratio $\text{HgS} : \text{Na}_2\text{S}$ is 1 : 2. According to R. Weber the solubility is conditioned by the formation of double salts which were afterwards studied by A. Ditte. The presence of sodium carbonate does not retard the dissolution of mercuric sulphide in sodium sulphide soln., but within certain limits a part of the mercury is precipitated if borax be present. A. Schrauf found that metacinnabarite is completely soluble in colourless potassium hydrosulphide; and all three crystalline modifications were found by E. T. Allen and J. L. Crenshaw to be soluble in soln. of potassium and sodium monosulphides. V. Stanek found white ammonium sulphide transforms the red into black sulphide at $150^\circ\text{--}200^\circ$ in a sealed tube. According to L. L. de Koninck, the addition of a large proportion of water to a soln. of alkali mercuric sulphide precipitates mercuric sulphide, but not if alkali hydroxide be also present. Ammonium chloride, according to K. Polstorff and K. Bülow, also precipitates mercuric sulphide from its soln. in alkali sulphides. M. Berthelot found that the precipitation begins when acetic acid is added to the soln. of alkali mercuric sulphide even if the soln. is alkaline, and it is complete in an acid soln. L. L. de Koninck also added that if the precipitation be rapid, the black sulphide appears; if slow, the red sulphide. E. Behrend estimated that a soln. of mercuric sulphide in sodium sulphide has a mgrm. of Hg-ions per 2×10^{17} litres for the conc. of the S'' -ions or the Hg'' -ions; J. Knox gave 1.7×10^{-27} gram-ions per litre, and L. Bruner, and J. Zawadzky gave 9.0×10^{-31} . J. Knox studied the solubility of mercuric sulphide in soln. of the alkali sulphides and in soln. of barium sulphide. He found the solubility in potassium sulphide soln. to be greater than in sodium sulphide soln. Expressing the results in mols per litre, J. Knox found with potassium sulphide :

Conc. of K_2S	.	.	.	1.0	0.5	0.25
Solubility HgS , red	.	.	.	0.4629	0.1588	0.04839
Solubility HgS , black	.	.	.	—	0.1836	0.06000

and with sodium sulphide :

Conc. of Na_2S	.	.	.	2.030	1.52	1.015	0.755	0.50	0.25	0.10
Solubility HgS , red	.	.	.	1.144	0.7832	0.4423	0.2878	0.1500	0.04544	0.00824
Solubility HgS , black	.	.	.	—	0.8561	0.5002	0.3336	0.1805	0.05622	0.01085

In the case of sodium sulphide soln. the anions HgS_2'' are formed, and this the more

with increasing dilution, and with the black sulphide more readily than with the red. The solubility decreases with rise of temp., so that the temp. coeff. between 25° and 33° is small and negative.

Conc. of Na ₂ S . . .	0.755	0.50	0.25	0.10
Solubility at 33° . . .	0.2828	0.1465	0.04360	0.007887
Solubility at 25° . . .	0.2878	0.1500	0.04544	0.00824

The solubility is augmented if sodium hydroxide be present.

Conc. of Na ₂ S . . .	1.015	0.755	0.50	0.25	0.10
Solubility HgS . . .	0.4423	0.2878	0.1500	0.04544	0.008241
with 0.5N-NaOH . . .	—	—	0.2843	0.1106	0.03962
1.0N-NaOH . . .	0.673	0.485	0.302	0.148	0.0563
4.67N-NaOH . . .	—	—	—	0.225	0.0903
7.7N-NaOH . . .	0.9167	—	0.4637	0.2369	0.09634

In soln. sat. with sodium sulphide, J. Knox found $[Hg^{++}][HgS_2^{--}] = 4 \times 10^{-53}$; and for the complex anion, $5.1 \times 10^{-54} [Hg^{++}][S'']^2 = [HgS_2^{--}]$. J. Knox calculated the equilibrium constant from the data of C. Immerwahr to be 7.0×10^{-28} ; and obtained for the solubility product $[Hg^{++}][S''] = 2.8 \times 10^{-54}$ at 25°. R. Abegg stated that the solubility of cinnabar in alkali sulphide soln. is proportional to the conc. of the S''-ions. The solubility of mercuric sulphide in soln. of sodium disulphide, Na₂S₂, is about half as great as in the corresponding soln. of sodium monosulphide, Na₂S. The solubility with barium sulphide soln. is virtually the same as with sodium sulphide soln.—being 0.008241 mol. HgS per litre with a soln. containing 0.1 mol. BaS.

E. F. Smith found that **sulphur monochloride**, S₂Cl₂, dissolves cinnabar. According to H. Feigl, a benzene soln. of sulphur chloride converts mercuric sulphide into a yellow compound, *mercuric sulphochloride*, HgS₂Cl₂; mercuric sulphide is also coloured yellow when allowed to stand in contact with sulphur chloride. A. Guerout found that it is not changed by aq. **sulphurous acid**. According to G. F. Hildebrandt, and W. T. Brande, cold conc. **sulphuric acid** does not act on red or black mercuric sulphide, but the hot acid develops sulphur dioxide with the sublimation of sulphur and the formation of mercuric sulphate—M. Berthelot did not detect the formation of hydrogen sulphide at any temp. E. Divers and T. Shimidz uobtained white sulphatosulphide, 2HgS.HgSO₄, with hot conc. sulphuric acid; and A. Schrauf obtained white mercuric sulphate by the action of boiling sulphuric acid on metacinnabarite. W. C. Moore detected no perceptible action with a mixture of 4N-HNO₃ and 4N-H₂SO₄ after 100 days at ordinary temp.; there is a slight action in 14 days at 25.75°; when boiled under a reflux condenser, the oxidation of the mercuric sulphide is rapid.

According to G. Gore,¹⁵ mercuric sulphide is insoluble in liquid **ammonia**, and G. F. Becker found it to be soluble in aq. ammonia when heated in a sealed tube at 145°–175°, but K. Heumann observed no action at ordinary temp. and press. H. Moissan found mercury reacts with **sulphammonium** at ordinary temp., forming a crystalline *mercury sulphammonium* which dissociates into black mercuric sulphide. G. F. Hildebrandt, and U. Antony and L. Niccoli said that cinnabar is not affected by long boiling with **nitric acid**; C. Barfoed observed no action when heated 48 hrs. with nitric acid of sp. gr. 1.52 at 70°–72°, and the precipitated sulphide is not attacked by conc. nitric acid of sp. gr. 1.52 after many hours' contact in the cold, but after 24 hrs. at 70°–75°, the sulphide becomes grey, and after standing another 24 hrs., sulphuric acid is formed, a trace of mercury is dissolved, and the solid residue is mercuric nitratosulphide, 2HgS.Hg(NO₃)₂. J. Torrey also stated that the precipitated black sulphide is changed by boiling dil. nitric acid into brown, yellow, or white nitratosulphide, which is again blackened by a boiling soln. of sodium carbonate. F. Gramp found that with nitric acid of sp. gr. 1.4 in a sealed tube at 120°, mercuric sulphide is rapidly and completely oxidized to mercuric sulphate; with an acid of sp. gr. 1.2, the residue has the composition HgO, 6HgS, 2Hg(NO₃)₂.

$12\text{H}_2\text{O}$. J. L. Howe found that mercuric sulphide is **not** changed by boiling with pure nitric acid (sp. gr. 1.42); the addition of one drop of dil. hydrochloric acid, however, causes the conversion of the sulphide into a yellowish-white compound, presumably $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgS}$; the further addition of 10 drops of hydrochloric acid causes the complete soln. of the yellowish compound. The same changes are brought about by dil. nitric acid containing a little hydrochloric acid as impurity. Similar observations were made by W. C. Moore with a mixture of nitric acid and potassium chloride—the mercuric sulphide is more or less vigorously oxidized—*vide supra* for the action of aqua regia. R. F. Weinland and L. Storz found no reduction occurred when mercuric sulphide is boiled with a soln. of **sodium arsenite**, Na_2AsO_3 . L. Storch found that cinnabar is dissolved by soln. of sodium or ammonium **thioarsenate**, **thioantimonate**, **thiostannate**, **thiomolybdate**, **thiotungstate**, and **thiovanadate**.

According to F. C. Vogel,¹⁶ when a mixture of mercuric sulphide and **carbon**—lampblack, or charcoal—is heated, decomposition occurs, mercury vapour is given off, and a large quantity of hydrogen sulphide is evolved—P. Berthier said that F. C. Vogel mistook carbon disulphide for hydrogen sulphide, and added that the decomposition is very incomplete. M. Berthelot found that freshly precipitated and well-washed mercuric sulphide does not dissolve in a soln. of **potassium cyanide**, nor does a soln. of potassium mercuric cyanide, K_2HgCy_4 , give a precipitate with hydrogen sulphide. T. Rosenblatt found mercuric sulphide to be soluble in a soln. of **potassium thiocarbonate**, and to be reprecipitated by carbon dioxide. H. C. Bolton found that cinnabar resists the action of **citric acid**, J. Schröder found cinnabar to be insoluble in **pyridine**. According to G. Rauter, cinnabar is not decomposed by **silicon tetrachloride**.

According to G. F. Hildebrandt,¹⁷ cinnabar is desulphurized when heated with **iron**, **copper**, **tin**, **lead**, **silver**, **bismuth**, or **antimony**, forming a sulphide, and mercury distils over. A. Eschka studied the action of iron. C. Karmarsch found that at ordinary temp. copper or **brass** is blackened by cinnabar only when impurities are present—*e.g.* potassium carbonate, but K. Heumann found that the vermilion loses its characteristic colour in contact with copper or brass; a slip (*i.e.* a suspension in water) of mercuric sulphide amalgamates copper; and metals generally desulphurize mercuric sulphide suspended in water—*e.g.* cinnabar suspended in water is immediately converted by **zinc** filings into a greyish-black powder; if the water is acidified the change is very rapid, and some hydrogen sulphide is formed. Powdered copper acts similarly on cinnabar suspended in water.

When cinnabar is ignited with an **alkali hydroxide** or **alkali carbonate**, P. Berthier¹⁸ found that mercury is given off, and a mixture of the alkali sulphide and sulphate is formed. According to E. F. Smith, the sulphur of cinnabar is quantitatively oxidized if the powder is placed in molten potassium hydroxide and the containing nickel dish be made the anode for the electrolysis. J. Walker found mercuric sulphide to be soluble in a soln. of sodium hydroxide in the presence of the sulphides of the arsenic group; the mercury is precipitated by adding sodium peroxide to the boiling soln. Calcium oxide acts: $4\text{CaO} + 4\text{HgS} = 4\text{Hg} + 3\text{CaS} + \text{CaSO}_4$. The decomposition is complete if the alkali or lime be mixed with some charcoal. P. Berthier also found that **lead oxide** under similar conditions furnishes sulphur dioxide and mercury, and leaves metallic lead and a fusible slag, which, if the lead oxide is not in great excess, contains undecomposed cinnabar.

According to A. Vogel, when cinnabar is heated with dry **stannous chloride**, mercuric chloride and a trace of sulphur dioxide are given off, and stannic sulphide is formed; and when cinnabar is boiled with an aq. soln. of stannous chloride, hydrogen sulphide and chloride are evolved and a brown mixture of undecomposed cinnabar and stannous chloride, mercury, and stannic oxide remains. When freshly precipitated mercuric sulphide is boiled with a soln. of **ferrous chloride**, J. B. Cammerer found only a trace of iron in the precipitate. F. Field found that soln. of **ferric chloride** or **cupric chloride** containing an excess of hydrochloric

acid are reduced when boiled for an hour with mercuric sulphide—sulphur separates at the same time; **chromic chloride** and **uranium chloride** are not affected. J. Hanus found a boiling soln. of ferric sulphate is not appreciably affected. E. Schürmann found mercuric sulphide at 100° is completely decomposed by a 0.1*N*-soln. of **palladious chloride**, but not by one of **silver nitrate** or **cupric sulphate**. According to P. A. Bolley, cinnabar is immediately blackened when immersed in a soln. of silver nitrate containing an excess of ammonia, and he recommends this as a test for cinnabar—silver sulphide, a basic mercuric nitrate, and a mercury amide are formed. Orpiment and stannic sulphide give the same reaction with silver nitrate soln., but without the ammonia.

The solubility of mercuric sulphide in soln. of various sodium sulphides has already been discussed. G. F. Becker¹⁹ assumed that compounds $n\text{Na}_2\text{S} \cdot \text{HgS}$ were formed, when $n=1, 2$, and 4, and possibly also 3 and $\frac{1}{2}$. J. Knox showed that aq. soln. contained the complex **sodium mercuric sulphide**, Na_2HgS_2 ; and he prepared the complex $2\text{Na}_2\text{S} \cdot 5\text{HgS} \cdot 3\text{H}_2\text{O}$, by concentrating a sat. soln. of mercuric sulphide in one of sodium sulphide, in vacuo over sulphuric acid, and removing the sodium sulphide by washing with oft-renewed absolute alcohol. The pale yellow crystals decompose in air, and they lose water in an atm. of hydrogen between 100° – 105° , and are then coloured brownish-black.

A number of potassium mercuric sulphides has been prepared. According to C. Brunner, the liquid which is decanted from the cinnabar, prepared by G. S. C. Kirchhoff's process, is evaporated and decanted from the first crop of crystals; it is then further concentrated, and a mass of fine silky needles is obtained. These are dried by press. between filter paper; the analysis corresponds with **pentahydrated potassium mercuric sulphide**, $\text{K}_2\text{S} \cdot \text{HgS} \cdot 5\text{H}_2\text{O}$. R. Weber made the crystals by dissolving freshly precipitated mercuric sulphide in a mixture of ammonium sulphide and potassium hydroxide. When the soln. is evaporated, ammonia is evolved and crystals of potassium chloride separate; when further conc., crystals of the pentahydrated sulphide appear, and they can be purified by re-crystallization from potassium hydroxide. R. Weber also mixed the freshly precipitated sulphide with a soln. of potassium hydroxide, and passed hydrogen sulphide through the soln. until all is dissolved—if too much hydrogen sulphide is introduced mercuric sulphide is precipitated because, said C. Barfoed, it has a low solubility in the hydrosulphide which is formed. The evaporation of the soln. furnishes the salt in question. R. Weber dissolved a mixture of equi-molar parts of sulphur and mercuric sulphide in an excess of molten potassium hydroxide, and evaporated the aq. soln. of the cold cake for crystals of the pentahydrate. According to R. Weber, the fine silky needles are deliquescent—probably because of the presence of free potassium hydroxide—they give off water when heated in a tube, and melt to a red liquid from which mercury, but not mercuric sulphide, sublimes. Water decomposes the salt with the separation of mercury and mercuric sulphide, according to C. Brunner, or of pentahydrated potassium pentamercuric sulphide, $\text{K}_2\text{S} \cdot 5\text{HgS} \cdot 5\text{H}_2\text{O}$, according to A. Ditte. A soln. of ammonium chloride acts like water (C. Brunner); neutral alkali hydroxide, sodium hydrophosphate, alkali hydrocarbonates, and borax soln. precipitate mercuric sulphide. A. Ditte prepared white silky needles of what he regarded, without analysis, as **heptahydrated potassium mercuric sulphide**, $\text{K}_2\text{S} \cdot \text{HgS} \cdot 7\text{H}_2\text{O}$, from a soln. of freshly precipitated mercuric sulphide in a cold conc. soln. of potassium sulphide. A. Ditte also made **monohydrated potassium mercuric sulphide**, $\text{K}_2\text{S} \cdot \text{HgS} \cdot \text{H}_2\text{O}$, in golden-yellow plates by crystallization from a soln. of freshly precipitated mercuric sulphide in a hot conc. soln. of potassium sulphide.

By keeping pentahydrated potassium mercuric sulphide for a long time in contact with a soln. of potassium hydroxide in a closed vessel, R. Schneider obtained pale olive-green six-sided plates, probably rhombic, of **potassium dimercuric sulphide**, $\text{K}_2\text{S} \cdot 2\text{HgS}$. The crystals melt, forming a dirty brown mass, mercury and mercuric sulphide sublime, and a potassium polysulphide remains as a residue.

Water decomposed the double sulphide, depositing mercuric sulphide; chlorine forms sulphur chloride, S_2Cl_2 , and mercuric and potassium chlorides; chlorine water oxidizes some of the sulphur to sulphuric acid; hydrochloric acid forms mercuric sulphide, hydrogen sulphide, etc.; aq. ammonia and potassium hydroxide separate mercuric sulphide; nitric acid acts like hydrochloric acid. A. Ditte also prepared black and red crystals of pentahydrated potassium pentamercuric sulphide, $K_2S \cdot 5HgS \cdot 5H_2O$. When mercuric sulphide is brought in contact with a dil. soln. of potassium sulphide, a certain quantity of the former is simply dissolved, but no other change takes place even if the substances are left in contact for several months. If, however, the alkaline soln. is moderately conc., the excess of mercuric sulphide is converted into brilliant black needles of the composition $K_2S \cdot 5HgS \cdot 5H_2O$, the change being more rapid the higher the temp. The crystals are larger and more brilliant the more slowly they are formed. They are decomposed by water, which gradually removes the alkaline sulphide and leaves a residue of mercuric sulphide, the decomposition taking place much more rapidly on heating. If the soln. of potassium sulphide is very highly conc. white needles of the heptahydrate are formed. Red needles of $K_2S \cdot 5HgS \cdot 5H_2O$, resembling the black needles in every respect except colour, are formed when a soln. of the alkaline sulphide containing an excess of mercuric sulphide is gradually heated to 35° – 40° , especially if a small quantity of vermilion is added. In such a soln., heated at 35° – 40° , but still clear, the formation of red or black needles is determined by adding a small quantity of vermilion or of the black crystals respectively. The colour of the crystals varies from bright red to deep cinnabar-red, according to the conc. of the soln. and the temp. When a mass of the black needles is allowed to stand in the alkaline sulphide soln. in a closed vessel for some time, those crystals which are in contact with the sides of the vessel are gradually converted into the red variety. These are stable in the alkaline liquid in the cold, but if heated they are converted into the black variety, the change being more rapid the more conc. the soln. If the alkaline sulphide soln. at the ordinary temp. contains but a small quantity of the compound HgS , K_2S , it yields on boiling a black deposit, which contains not only black crystals of $K_2S \cdot 5HgS \cdot 5H_2O$, but also mercuric sulphide in black hexagonal plates. If such a soln. is gradually heated in a water-bath and mixed with a trace of vermilion, a red deposit is obtained consisting of needles of the composition $K_2S \cdot 5HgS \cdot 5H_2O$, and red transparent rhomboidal lamellæ of mercuric sulphide. With a certain degree of conc. of the soln., the latter is practically the sole product. It is evident, therefore, that the simple sulphide, HgS , and the double sulphide, $K_2S \cdot 5HgS$, can be obtained simultaneously as either red or black crystals, but when one is red the other is red, and when one is black the other is black.

According to U. Antony and A. Lucchesi, when an aq. soln. of potassium or sodium gold sulphide, $3M_2S \cdot Au_2S$, is treated with mercuric chloride, a red flocculent precipitate—possibly **gold mercurous sulphide**, $3Hg_2S \cdot Au_2S$ —is formed. It is not attacked by acids, but is decomposed by aqua regia. According to C. F. Rammelsberg, an aq. soln. of barium sulphide dissolves black mercuric sulphide; and, according to R. Wagner, cinnabar does not dissolve in that menstruum in the cold, but it does so readily at 40° – 50° . J. Knox—*vide supra*—measured the solubility at 25° . The soln. on evaporation furnishes crystals of **pentahydrated barium mercuric sulphide**, $BaS \cdot HgS \cdot 5H_2O$. The compound is decomposed by acetic acid with the separation of mercuric sulphide; and when the soln. is treated with an acid, or sat. with hydrogen sulphide, black mercuric sulphide is precipitated. According to J. Petersen, and H. J. Burkart, a **zinc mercuric sulphide**, $ZnS \cdot 6HgS$, occurs as the mineral *guadalcazarite*, but the latter is best regarded as a mixture of metacinnabarite and a little zinc sulphide.

§ 28. Mercuric Chlorosulphide, Bromosulphide, and Iodosulphide

H. Rose¹ showed that when hydrogen sulphide is passed into a soln. of mercuric chloride, the precipitate, at first white, changes to yellow, then brown, and finally black. The white precipitate is regarded as **mercuric chlorodisulphide**, $2\text{HgS} \cdot \text{HgCl}_2$, or **mercuric disulphochloride**; and the reaction is symbolized:

A. Naumann regards mercuric chlorodisulphide as the mercuric salt $\text{Hg}(\text{SHgCl})_2$ of **hydrochlorosulphomercuric acid**, HSHgCl ; J. S. F. Pagenstecher noted a similar reaction with alkaline sulphides. The continued action of hydrogen sulphide results in the production of black mercuric sulphide, $\text{Hg}_3\text{S}_2\text{Cl}_2 + \text{H}_2\text{S} = 2\text{HCl} + 3\text{HgS}$. Instead of using an aq. soln. of mercuric chloride, F. Bezold obtained a similar result by passing hydrogen sulphide into a soln. of mercuric chloride in methyl acetate; M. Hamers, A. Naumann, and E. Alexander used a soln. in ethyl acetate; E. Vogt, a soln. in acetone; and A. Naumann, soln. in ether, benzene, benzonitrile, or methylal; A. Colson also used a benzene soln. According to T. Poleck and C. Goercki, if chlorine is passed into water with freshly precipitated mercuric sulphide in suspension, the latter assumes a bright yellow colour, and finally dissolves. The yellow product has the composition $\text{HgCl}_2 \cdot 2\text{HgS}$. Hence mercuric chlorodisulphide represents an intermediate stage in the conversion of mercuric chloride to sulphide, and conversely, T. Poleck and C. Goercki further found that if a mol of mercuric sulphide is digested with a soln. of a mol of mercuric chloride, half the latter remains in soln.; if, however, 2, 3, 4, or 5 mols of the sulphide are employed, no chloride remains in soln., and bright yellow products are formed with $\text{HgS} : \text{HgCl}_2$ in the molar proportions 2 : 1, 3 : 1, 4 : 1, and 5 : 1 respectively. It is not clear if these products are chemical individuals, more probably they are solid soln. of mercuric sulphide with the disulphochloride. P. Jolibois and P. Bouvier could find no products other than mercuric sulphide, HgS , and the chlorodisulphide, $2\text{HgS} \cdot \text{HgCl}_2$, as a result of the action of hydrogen sulphide on a dil. soln. of mercuric chloride.

T. Poleck and C. Goercki supposed them to be chemical individuals because they are insoluble in hot and cold water; indeed, they are not changed when heated with water in a sealed tube at 200° . They are not altered by boiling with a soln. of sodium chloride, but in a sealed tube at 190° , they are resolved into their constituents. When heated to 170° with a soln. of potassium iodide, the products are decomposed, $2\text{HgS} \cdot \text{HgCl}_2 + 4\text{KI} = 2\text{HgS} + 2\text{KCl} + \text{K}_2\text{HgI}_4$. In all cases the red form of mercuric sulphide is obtained; freshly precipitated mercuric sulphide does not become red when treated in the same way; nor is the product obtained by precipitating mercuric chloride with sodium thiosulphate.

Mercuric chlorodisulphide has been produced in numerous other reactions. R. Schneider obtained it by melting in a sealed tube a mixture of 8-10 parts of mercuric chloride with one part of cinnabar or black mercuric sulphide. The powdered mass is washed with water to remove the excess of mercuric chloride. R. Palm made it by the action of a hot soln. of mercuric chloride in excess on sublimed cinnabar, and by adding hydrochloric acid or a soluble chloride to a soln. of mercuric sulphide in one of mercuric acetate. F. Raschig produced it by the action of a soln. of cupric chloride, and J. B. Cammerer by the action of a neutral soln. of ferric chloride on mercuric sulphide; T. Poleck and C. Goercki found that when soln. of sodium thiocarbonate and mercuric chloride are mixed, $\text{HgCl}_2 + \text{Na}_2\text{CS}_3 + 2\text{H}_2\text{O} = \text{HgS} + 2\text{NaCl} + \text{CO}_2 + 2\text{H}_2\text{S}$; but if a large excess of dry mercuric chloride is treated with a soln. of sodium thiocarbonate, mercuric chlorodisulphide is produced. The same compound is formed when a soln. of 2 mols of mercuric chloride is mixed with a soln. of one mol of sodium thiosulphate. N. Tarugi obtained mercuric chlorodisulphide by treating a cold neutral soln. of mercuric chloride with thioacetic acid, and also by the action of dil. hydrochloric acid on mercuric thioacetate; and K. Preis, by heating sodium sulphoarsenate with an excess of mercuric chloride.

Mercuric chlorodisulphide is a white friable mass, and when higher proportions of mercuric sulphide are present, the colour is yellow. M. Hamers, and F. Bezold found that the colour darkens on exposure to light. H. Rose noted that when slowly heated in a glass tube, mercuric chlorodisulphide is decomposed into its constituents, both of which sublime, the chloride collecting above the sulphide. M. Hamers, F. Bezold, and E. Alexander noted that the compound can be sublimed with but partial decomposition if rapidly heated. There are some extraordinarily conflicting statements about the properties of this compound. T. Poleck and C. Goercki—*vide supra*—found water had no action, whereas F. Bezold and M. Hamers said that boiling water resolves the complex salt into its components. Again, H. Rose said that it is not dissolved or decomposed by cold or hot, dil. or conc. sulphuric hydrochloric, or nitric acid; that it is decomposed by boiling nitric acid, and that most of the sulphur is oxidized to sulphuric acid; M. Hamers, that with boiling dil. sulphuric, hydrochloric, or nitric acid the salt is decomposed and mercuric chloride passes into soln.; E. Alexander said that although the salt is insoluble in water and in sulphuric acid, it is partly soluble in hydrochloric and nitric acids, and easily soluble in aqua regia; N. Tarugi said that it is soluble only in aqua regia; and E. Vogt that it is insoluble in conc. acids and in aqua regia.

H. Rose showed that when mercuric chlorodisulphide is suspended in water, and treated with hydrogen sulphide, it is converted into black mercuric sulphide; it is also blackened by soln. of alkali hydroxides, or carbonates, forming, according to M. Hamers, mercuric oxide and sulphide, and R. Palm said that a soln. of potassium cyanide extracts the oxide and leaves the sulphide. The carbonates act much more slowly than the hydroxides at ordinary temp. E. Vogt found that when heated with calcium oxide, all the mercury is expelled. H. Rose showed that when heated in a current of chlorine gas, sulphur and mercuric chlorides are formed: $2\text{HgS} \cdot \text{HgCl}_2 + 3\text{Cl}_2 = \text{S}_2\text{Cl}_2 + 3\text{HgCl}_2$. For the action of a soln. of sodium chloride, and of potassium iodide, *vide supra*.

In addition to T. Poleck and C. Goercki's $3\text{HgS} \cdot \text{HgCl}_2$, $4\text{HgS} \cdot \text{HgCl}_2$, $5\text{HgS} \cdot \text{HgCl}_2$, a number of other sulphochlorides or chlorosulphides has been reported, but their individuality has not been established. For example, R. E. Hughes obtained a greenish-yellow precipitate by the action of hydrogen sulphide on a soln. of mercuric chloride in absolute

alcohol. This has a composition approximating to HgS.HgCl_2 . C. Barfoed reported a yellow product, 12HgS.5HgCl_2 , to be formed by the action of dil. hydrochloric acid on the compound of mercuric nitrate with mercuric sulphide. He assumes this to be a mixture of 2HgS.HgCl_2 with 3HgS.HgCl_2 . F. Bodroux reported $\text{Hg}_2\text{S}_5.\text{HgCl}_2$ to be formed by the action of calcium polysulphide on an excess of cold soln. of mercuric chloride. F. Capitaine said that a compound, Hg_2SCl_4 , is formed when an intimate mixture of mercuric chloride and sulphur is heated; and by the action of sulphur chloride, SCl_2 , on mercurous chloride. J. E. Gilpin said that the same compound is produced by heating a mixture of mercuric chloride and arsenic pentasulphide in a retort—arsenic trichloride first sublimes.

According to G. Franceschi, the addition of a few drops of an alcoholic soln. of hydrogen sulphide to an alcoholic soln. of mercuric bromide produces a slight milkiness: $\text{H}_2\text{S} + 2\text{HgBr}_2 = 2\text{HgBr} + \text{S} + 2\text{HBr}$; when more of the hydrogen sulphide soln. is added, the canary-yellow bromodisulphide is formed, $\text{H}_2\text{S} + 6\text{HgBr} + 3\text{S} = 2(2\text{HgS.HgBr}_2) + 2\text{HBr}$; and if an excess of the hydrogen sulphide soln. is added, black mercuric sulphide is formed: $\text{H}_2\text{S} + 2\text{HgS.HgBr}_2 = 3\text{HgS} + 2\text{HBr}$. H. Rose, R. Palm, A. Naumann, M. Hamers, and F. Bezold obtained similar results by using a soln. of mercuric bromide in place of the chloride. The product is **mercuric bromodisulphide**, 2HgS.HgBr_2 , or $\text{Hg}(\text{S.HgBr})_2$.

H. Rose digested mercuric iodide with an insufficient quantity of potassium sulphide, and obtained a yellow powder taken to be **mercuric iodosulphide**, HgS.HgI_2 . C. F. Rammelsberg obtained a similar product by dissolving mercuric oxide in a hydrochloric acid soln. of mercuric iodide containing a little hydrogen sulphide; and A. Kekulé, by diluting a soln. of mercuric hydriodide, sat. with hydrogen sulphide. R. Palm obtained a fiery orange-coloured iodosulphide by the action of a soln. of mercuric iodide on cinnabar. This product was not analyzed. F. Bezold obtained **mercuric iododisulphide**, 2HgS.HgI_2 , by passing dry hydrogen sulphide into a soln. of mercuric iodide in methyl acetate; and M. Hamers used ethyl acetate. R. Palm prepared the same compound by adding hydriodic acid or an alkali iodide to a soln. of mercuric sulphide in one of mercuric acetate. G. Franceschi obtained results with mercuric iodide analogous to those obtained with mercuric bromide. H. Köhler obtained a yellow product which was thought to be **mercuric chloriodosulphide**, Hg_2SCHI , by the action of hydrogen sulphide on a dil. hydrochloric acid soln. of mercuric chloriodide, HgClI . O. Förster mixed a soln. of allyl thiocyanate in ammoniacal alcohol, or an ammoniacal soln. of allyl thiocarbamide with a soln. of mercuric and potassium iodides, and obtained a lemon-yellow precipitate, **mercuric aminiododisulphide**, $2\text{HgS.HgI}_2.\text{NH}_3$, which becomes orange-yellow when dried in darkness. The product is blackened by exposure to light, or by treatment with potassium cyanide.

P. C. Ray² prepared *mercury mercaptide nitrite*,

as a white precipitate by adding a dil. aq. soln. of thiocarbamide to a conc. soln. of sodium mercuric nitrite. When this compound is repeatedly boiled with ethyl iodide, and extracted each time with acetone, it furnishes a yellow granular powder, **mercuric diiododisulphide**, $\text{Hg}_2\text{I}_2\text{S}_2$, which slowly darkens in diffused daylight and more rapidly in sunlight. The reaction is *phototropic*, for the original yellow colour is restored in darkness. P. C. Ray and P. K. Sen prepared the corresponding **mercuric dichlorodisulphide**, $\text{Hg}_2\text{Cl}_2\text{S}_2$, but found that this immediately forms **mercuric hexachlorodioxihexasulphide**, $(3\text{SHgCl.HgO})_2$. Three mols of mercuric dichlorodisulphide first unite with two mols of mercuric chloride, and the product reacts with water:

By treating **mercuric dichloratosulphide**, $\text{Hg}(\text{ClO}_4)_2 \cdot \text{HgS}$, prepared by the action of hydrogen sulphide on a soln. of mercuric chlorate, with chlorides, nitrates, or sulphates, G. McP. Smith obtained **mercuric dichlorodisulphide**, $\text{HgCl}_2 \cdot 2\text{HgS}$; and **mercuric dinitratodisulphide**, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgS}$.

§ 29. Mercurous Sulphate

A sulphate of mercury appears to have been made in the fourteenth century by J. de Roquetaillade,¹ for *cum spiritu vitrioli Romani fit magnum adminiculum, ad congelandum Mercurium in substantia, et facit ipsum album sicut nivem*. The Paracelsian school—Basil Valentine, etc.—applied the term *turpethum minerale*, *mineral turpeth*, *mineral turbite*, *turpeth*, or *turbite* to a basic sulphate, but H. Mynsicht used it for other products, and A. Libavius stated:

Turpeth, a word of Asiatic (should be Persian) origin and the name given to a preparation from the bark or root of a certain ferulaceous plant (*i.e.* of the reed tribe), has slipped into the nomenclature of chemistry, in all probability because of the similarity of its effects with those of a certain secret preparation of mercury. In order to prevent confusion of this latter with the vegetable medicine, the word “mineral” has been added.

A. F. de Fourcroy and L. J. Thénard² spoke of three sulphates of mercury, *le sulfate neutre* (mercurous sulphate), *le sulfate avec excès d'acide* (mercuric sulphate), and *le sulfate avec excès d'oxyde* (basic mercuric sulphate). In the dismantling of a mercury furnace at Idria a crust, filled with geodes of small pellucid crystals of **mercurous sulphate**, Hg_2SO_4 , was found in the brickwork by G. Seyfriedsberger. Dil. sulphuric acid has scarcely any action on mercury in the cold, but the boiling conc. acid forms sulphur dioxide and mercurous sulphate, Hg_2SO_4 , if the mercury is in excess, and mercuric sulphate, HgSO_4 , if the acid is in excess—*vide* C. Baskerville and W. H. Miller for the action of sulphuric acid on mercury. If two parts of mercury be heated with one to two parts of sulphuric acid until over half is converted into a solid salt, and the mercury and sulphuric acid poured off, mercurous sulphate remains; this is washed with a little cold water. If the mixture has been evaporated to dryness, the product is a mixture of mercurous and mercuric sulphates; if two parts of mercury have been used to one of acid, some free mercury remains; the mercurous salt is gradually converted to the mercuric salt by the hot acid. It is troublesome to prepare mercurous sulphate free from mercuric sulphate by this process, and E. Divers and T. Shimidzu prepared it in the cold by leaving together mercury and fuming sulphuric acid rich in trioxide in a covered and cool vessel. When the metal has all disappeared, the uncovered vessel is left in a warm place to expel the last portions of the sulphur trioxide. It is desirable so to apportion the acid as

to have as little of the trioxide left unconsumed as possible, so that where the mercury taken has proved much too small, more had better be added, still avoiding excess. The product needs only to be transferred to water and washed to be ready for use. F. E. Smith prepared mercurous sulphate by a similar process. H. S. Carhart and G. A. Hulett electrolyzed dil. sulphuric acid (1 : 6) over a layer of mercury which serves as anode, while a platinum wire served as cathode; the current density was 0.1 amp. per sq. cm. A similar process was used by G. A. Hulett, H. von Steinwehr, F. A. Wolff, A. Brochet and J. Petit, and G. Maneuvrier and J. Chappius.

L. A. Planché prepared mercurous sulphate by triturating a mixture of 18 parts of mercuric sulphate, 6 of water, and 11 of mercury. R. J. Kane prepared mercurous sulphate by treating a soln. of mercurous nitrate with sulphuric acid or sodium sulphate, and washing the precipitate with water. G. A. Hulett dropped an acidified soln. of mercurous nitrate with constant stirring into 1-6 per cent. sulphuric acid; F. E. Smith, A. de Schulten, R. Varet, and H. von Steinwehr used similar processes. H. Rose triturated crystallized mercurous nitrate with sodium sulphate and dissolved out the sodium nitrate with water. G. Denigès obtained mercurous sulphate by the action of formaldehyde on mercuric sulphate. The reduction proceeds slowly in the cold, rapidly when heated.

C. J. J. Fox recommended purifying commercial mercurous sulphate by heating it with dil. sulphuric acid and pure mercury for some days in a sealed tube or closed flask at 120°-150°. The mixtures should be frequently shaken. The liquid is decanted off, and the solid triturated in a mortar with dil. sulphuric acid two or three times, and then many times with a sat. soln. of cadmium sulphate. The product is then washed with water in a suction funnel. H. S. Carhart has also described the purification of mercurous sulphate for use in Weston's or Clark's standard or normal cells.

Mercurous sulphate appears as a white crystalline powder, which consists of minute monoclinic prisms. G. Seyfriedsberger³ thought that the **crystals** he found in the Idrian furnace were rhombic, but A. de Schulten showed that they are monoclinic, with axial ratios $a:b:c=0.9002:1:1.4086$, and $\beta=91^\circ 45'$. G. Seyfriedsberger's specimen had a **specific gravity** 8.353 at 21°/19°; and A. de Schulten's sample 7.121 at 15°; while L. Playfair and J. P. Joule gave 7.560 at 3.9°. According to J. Traube, the sp. gr. of a 0.070 per cent. soln. is 0.99985 at 15°, and the **molecular solution volume** is 12.6. In studying the **action of heat**, J. L. Gay Lussac found that the salt fuses to a deep reddish-brown liquid at a dull red heat and immediately decomposes into sulphurous acid, oxygen, and mercury, together with a little sulphuric acid. G. A. Städelér found that the fused mass freezes to a white crystalline solid. E. Cohen and co-workers found the **specific heat** to be 0.0640 at 18.5°-22.5°, and the **molecular heat** 31.83. H. Schottky found the mol. ht., C , to be 30.94; and the values at low temp., determined by F. Pollitzer, were 16.74 at -190°; 17.15 at -188°; 26.1 at -74°; and 25.9 at -70°. According to R. Varet, the **heat of formation** is $2\text{Hg}_{\text{liq.}} + 2\text{O}_{2\text{gas}} + \text{S}_{\text{solid}} = \text{Hg}_2\text{SO}_4 + 175$ Cals.; and $\text{HgSO}_{4\text{solid}} + \text{Hg}_{\text{liq.}} = \text{Hg}_2\text{SO}_4 + 9.9$ Cals. A. de Schulten found mercurous sulphate has a positive **double refraction**. J. A. Wilkinson stated that mercurous sulphate has a yellow **fluorescence** under the influence of the cathode rays, and there is also a yellow light emitted when the salt is formed by electrolysis. G. A. Städelér showed that mercurous sulphate becomes grey under the action of light, probably with the simultaneous formation of mercuric sulphate, and H. S. Carhart found the darkened sulphate gives too high an e.m.f. when used in Weston's standard cell, although S. Skinner said the change is so small as to have a negligible effect on Clark's standard cell. According to S. Skinner, mercurous sulphate is also darkened by exposure to **ultra-violet rays**, sunlight, and the light from the electric arc, as well as to **radium radiations**; the darkening is independent of the presence of air; he does not think that the darkening is due to the production of mercury and a mercuric salt, but he believes that a dark sub-salt or a polymeric form may be produced. F. E. Smith said that the **depolarizing effect** of mercurous

sulphate is independent of its mode of preparation, and H. von Steinwehr added that the observed irregularities are dependent on differences in the grain-size of the salt. G. A. Hulett, and P. J. H. van Ginneken have studied the depolarizing action of mercurous sulphate—*vide* standard cells.

The action of water on mercurous sulphate ; basic mercurous sulphates.—The solubility of mercurous sulphate in water is small. C. R. A. Wright and C. Thompson⁴ found 0.47 gm. is dissolved per litre at 18°; N. T. M. Wilsmore, 0.39 gm. per litre; and M. Barre found with Hg_2SO_4 as the solid phase 100 grms. of a sat. soln. contained :

	16.5°	33°	50°	75°	100°
Hg_2SO_4 . . .	0.055	0.060	0.065	0.074	0.092 grm.
H_2SO_4 . . .	0.008	0.018	0.037	0.063	0.071 „

J. L. Proust, and M. Donovan supposed the dirty yellow mass obtained by the long-continued action of boiling water on mercurous sulphate is a basic mercurous sulphate, but H. Rose regarded it as a mixture of mercury and a basic mercuric sulphate. According to R. J. Kane, no basic salt is obtained by treating mercurous sulphate either with cold or with boiling water. According to A. Gouy, mercurous sulphate is decomposed by water with formation of a yellow basic sulphate, **mercurous hydroxy-sulphate**, $\text{Hg}_2\text{O} \cdot \text{Hg}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, which resembles basic mercuric sulphate, but has a marked greenish tinge. Equilibrium is established when the water contains 0.410 gm. of mercury and 0.164 gm. of sulphuric acid per litre. Water which contains 0.08 gm. of sulphuric acid per litre does not convert the normal into the basic salt, and a higher proportion of acid converts the basic salt into the normal. When treated with dil. sulphuric acid, the yellow basic salt becomes white, and is thus readily distinguished from basic mercuric sulphate. M. Barre confirms the formation of the basic sulphate indicated by A. Gouy, but he believes that the action is more complex, because some metallic mercury is formed, which, at 50°, imparts a yellowish-green coloration. A. J. Cox found that the hydrolysis furnishes the oxysulphate, $2\text{Hg}_2\text{O} \cdot \text{SO}_3 \cdot \text{H}_2\text{O}$, or $2\text{Hg}(\text{OH}) \cdot \text{Hg}_2\text{SO}_4$, or $\text{Hg}_2\text{O} \cdot \text{Hg}_2\text{SO}_4 \cdot \text{H}_2\text{O}$. According to G. A. Hulett, the formation of the hydroxysulphate introduces an uncertain factor in the standard cell. The presence of the oxysulphate in aq. soln. is evidenced by the presence of free sulphur acid—*vide* M. Barre's data above. A. Gouy said that 0.004 gm. of the basic sulphate dissolves in a litre of water at -20° , and if $\frac{1}{10}\text{N}$ -sulphuric acid is present, hydrolysis does not occur, and the basic sulphate is converted into the normal sulphate. L. W. Pissarjewsky found that the hydrolysis is smaller in alcohol or glycerol soln. than in aq. soln. R. J. Kane claimed to have made **dihydrated mercurous sulphate**, $\text{Hg}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$; but he probably analyzed an imperfectly dried sample.

Many of the so-called basic salts recorded in the literature are mixtures of two or more phases, and the systems analyzed were not always in equilibrium; and even if the systems were in equilibrium, it was not possible to distinguish between chemical compounds and mixtures of two solid phases because of the absence of any distinguishing test. The phase rule has furnished a light to guide the footsteps of the investigator along this intricate path. Theory has taught the right practice. As a result, many older descriptions of alleged compounds are unsatisfactory. In the special case where basic salts are precipitated from soln. by the hydrolytic action of water—*e.g.* antimony trichloride, bismuth nitrate, mercury salts, etc.—the system will have three components, *C*, and three phases, *P*, and since for bivalent systems, $P=C$, it follows from the phase rule (1. 8, 5): (1) If the compositions of the soln. in different experiments are the same while the compositions of the precipitates vary, the soln. will form one phase, and the precipitate will be a mixture of two phases. (2) If the compositions of the soln. in different experiments are different, while the precipitates have the same composition, the precipitate will be a chemical individual. (3) If the compositions of the soln. and of the precipitates vary, the precipitate will be a single phase of variable composition, *i.e.* a solid soln. or mixed crystal.

In the experimental work, soln. of known composition are mixed in flasks and agitated until they are in equilibrium. The flasks are kept the whole time at a uniform temp. and the solid matter allowed to settle. Portions of the liquid are withdrawn for analysis, and the solid is analyzed after it has been separated as free as possible from the mother liquid, say, by press. between porous tiles, by whirling in a centrifuge, etc. Washing the solid may alter the composition of the precipitate.

It is vitally important to have definite evidence that the system is really in a state of equilibrium when the liquid and solid are analyzed. The test for equilibrium is that the composition of the precipitate and soln. is independent of the order in which they are mixed provided that the components are present in eq. amounts, and the temp. are the same. The condition of equilibrium will be the same when approached from both ends; for example, with bismuth nitrate and water, the composition of the oxynitrate will be the same whether bismuth nitrate be mixed with water, or bismuth oxide with dil. nitric acid. In the case of mercurous sulphate and water, A. J. Cox represented the relation between the composition of aq. soln. by the abscissæ, and that of the precipitates by the ordinates. A change in both these variables occurs when the composition of soln. or precipitate changes; and to interpret the results, it is necessary to know only if the composition of the soln. and precipitate changes from experiment to experiment. In representing the composition of soln. and precipitate by a curve, horizontal lines show that compositions of the soln. are variable and of the precipitates constant, and therefore the latter are chemical individuals; vertical lines show that the compositions of the soln. are constant and of the precipitates variable, so that the latter are mixtures of two or more variables; and sloping lines represent the compositions of solid soln. In Fig. 36, the ordinates represent the number of mols of $(\text{H}_2, \text{Hg}_2)\text{SO}_4$ per litre of soln., and the abscissæ, the increased basicity x of the solid phase, i.e. $2\text{Hg}_2\text{SO}_4 - x\text{SO}_3$. The diagram shows that no basic salt other than $\text{HgO} \cdot \text{Hg}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ is formed by the hydrolysis of mercurous sulphate between 15° and 25° .

FIG. 33.—Basic Salts of Mercurous Sulphate at 25° .

The chemical reactions of mercurous sulphate.—According to G. A. Hulett, mercurous sulphate in the presence of mercury is not oxidized by exposure to air; and H. S. Carhart stated that it can be preserved under dil. sulphuric acid (1 : 6) in darkness. According to S. Hada, moist mercurous sulphate becomes dark brown when exposed to a strong light, and that which has become yellow by treatment with water becomes greenish and then dark brown. The effect is superficial, and may be due to dissociation of the mercurous salt into mercuric salt and water. When heated to 150° in oxygen, with water and a little sulphuric acid, in a sealed tube, about 1.5 per cent. was oxidized. A. Mailfert found that the salt was oxidized by ozone to mercuric sulphate and oxysulphate. Mercurous sulphate is abundantly soluble in hot sulphuric acid, and part separates out as crystals when the soln. cools, and part is precipitated when water is added to the cold soln. K. Drucker showed that the solubility of mercurous sulphate increases to a maximum with increasing acidity of the soln., thus, with a soln. containing 1.96 grms. H_2SO_4 per litre, 0.41 grm. of salt was dissolved per litre; with 4.90 grms. H_2SO_4 per litre, 0.44 grm. of salt was dissolved; and with 8.04 grms. per litre, 0.40 grm. of salt was dissolved. P. Braham claimed to have made rhombic prisms of mercurous hydrosulphate,

HgHSO_4 , by allowing sulphuric acid with a trace of nitric acid to stand in the cold in contact with mercury for two years. This acid sulphate was found by J. Kendall and A. W. Davidson to be the solid phase in sulphuric acid soln. of this salt, and they found the f.p. of different mixtures to be :

Per cent. Hg_2SO_4	0.68	0.82	1.02	1.18	1.41	1.77	2.17
F.p.	20.0°	27.0°	34.9°	40.1°	47.7°	56.8°	63.3°

Soln. containing over 1.7 molar per cent. HgSO_4 rapidly became cloudy on heating owing to the oxidation of mercurous sulphate to the less soluble mercuric salt. The acid sulphate forms a white powder when exposed to the air ; at 100° it gives off 5 per cent. of water in 5 mins. ; sodium carbonate and potassium hydroxide give black precipitates ; and it is attacked by carbon disulphide, ether, and amyl alcohol. K. Drucker found that a litre of a soln. of 34.87 grms. of **potassium sulphate** dissolves 0.45 gm. of mercurous sulphate which is a little less than the 0.58 gm. obtained with water alone. M. Barre's results for the solubility of mercurous sulphate in aq. soln. of potassium sulphate are shown in Table XI, expressed as grams of salt

TABLE XI.—SOLUBILITY OF MERCUROUS SULPHATE IN AQUEOUS SOLUTIONS OF POTASSIUM SULPHATE (Grams of salt per 100 grms. of sat. soln.).

15°			33°			75°

per 100 grms. of sat. soln. M. Barre stated that there is here no evidence of the formation of a double salt. A. Gouy found that a sat. soln. of **zinc sulphate** or of **cadmium sulphate** decomposes mercurous sulphate much less readily than water, and it dissolves more of the unchanged salt—and according to G. A. Hulett, a sat. soln. of cadmium sulphate dissolves about five times as much salt as does water. G. Bredig and J. W. Brown noted the catalytic oxidation of organic substances in the presence of sulphuric acid and mercurous sulphate. H. W. F. Wackenroder found mercurous sulphate dissolves in dil. **nitric acid**, and is almost wholly re-precipitated by the addition of dil. sulphuric acid. A. F. de Fourcroy obtained a grey product by the action of aq. **ammonia** ; and, according to H. Saha and K. N. Choudhuri, conc. ammonia forms $2\text{HgO} \cdot (\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$. R. J. Kane believed that oxymercuroammonium sulphate, $\{\text{NH}_2(\text{Hg}_2\text{OHg}_2)\}_2\text{SO}_4$, is formed : $4\text{Hg}_2\text{SO}_4 + 8\text{NH}_3 + 2\text{H}_2\text{O} = \{\text{NH}_2(\text{Hg}_2\text{OHg}_2)\}_2\text{SO}_4 + 3(\text{NH}_4)_2\text{SO}_4$; but L. Pesci, and J. Lefort believed that the product is only a mixture. N. Tarugi also obtained **ammonium mercurous diamminoxysulphate**, $3\text{Hg}_2\text{O} \cdot 2(\text{NH}_4)\text{HgSO}_4 \cdot 2\text{NH}_3$, by the action of ammonia on ammonium mercurous diamminopersulphate. The white powder is insoluble in cold or hot, dil. or conc. nitric or sulphuric acid, but is soluble in hydrochloric acid.

§ 30. Mercuric Sulphate

G. Seyfriedsberger¹ obtained a white mass of rhombic crystals of **mercuric sulphate**, HgSO_4 , in the brickwork of a dismantled mercury furnace at Idria. J. G. Leonhardi, and G. F. Hildebrandt observed that when one part of mercury is heated with $1\frac{1}{2}$ parts of sulphuric acid, and evaporated to dryness, white mercuric sulphate is obtained. M. Geiseler showed that if a smaller proportion of acid is employed the product contains mercury or mercurous sulphate. R. Varet heated 5 parts of mercury with 3 parts of conc. sulphuric acid and a little nitric acid. A. J. Cox evaporated mercury repeatedly with conc. sulphuric acid, and washed the resulting mercuric sulphate with 7N-sulphuric acid on a suction funnel—*vide* the action of sulphuric acid on mercury. M. Geiseler evaporated to dryness a mixture of mercuric oxide with about half its weight of sulphuric acid; H. Eissfeldt obtained crystals of mercuric sulphate by treating many mercuric compounds with sulphuric acid—*e.g.* C. A. Cameron evaporated a soln. of basic mercuric sulphate in selenic acid, or basic mercuric selenate in sulphuric acid. K. Kahle purified mercuric sulphate from basic sulphate by treatment with dil. sulphuric acid.

Mercuric sulphate appears as an opaque mass, in white hygroscopic needle-like crystals, or, according to C. Hoitsema,² in white rhombic plates. L. Playfair and J. P. Joule gave 6.466 for the **specific gravity** at 3.9°; and G. Seyfriedsberger, 5.995 at 21°/19°. According to C. F. Mohr, the **action of heat** on mercuric sulphate is to change the colour from yellow, and then red; and at a bright red-heat, J. L. Gay Lussac found that it decomposes into mercury, mercurous sulphate, and sulphur dioxide.

The **heat of formation**, according to M. Berthelot, is $\text{HgO} + \text{H}_2\text{SO}_4 = \text{H}_2\text{C} + \text{HgSO}_4 + 2.6$ Cals., and, according to R. Varet, $\text{Hg}_{\text{liq.}} + \text{S}_{\text{solid}} + 2\text{O}_{2\text{gas}} = \text{HgSO}_4 + 166.1$ Cals. R. Varet found 4.9 Cals. for the heat of soln. $\text{HgSO}_4 + 4\text{H}_2\text{SO}_4$.

Mercuric sulphate was found by R. Phillips³ to be decomposed by **water** into

the basic salt, *turpeth mineral*, $2\text{HgO} \cdot \text{HgSO}_4$, and a soln. of an acid salt. M. Geiseler obtained a 68 per cent. conversion to the basic sulphate. K. Thümmel showed that the basic salt appears to contain a greater proportion of mercuric oxide, the more water employed in the decomposition of the sulphate. A. Ditte showed that the production of turpeth mineral ceases when the sulphuric acid simultaneously formed: $3\text{HgSO}_4 + 2\text{H}_2\text{O} \rightleftharpoons 2\text{HgO} \cdot \text{HgSO}_4 + 2\text{H}_2\text{SO}_4$, has a certain conc.—at 12° , 67 grms. SO_3 per litre—if the acid is more or less conc. than this, the normal sulphate is dissolved or decomposed. H. le Chatelier showed that the soln. contains mercuric sulphate, not the basic sulphate; and that the quantity of acid necessary to prevent the decomposition of a salt increases at first with an increase in the proportion of water; but it does not increase indefinitely, and tends towards a limit. This limit may be due to a partial dissociation of the hydrates of the acid, or to the comparative insolubility of a particular salt. He further showed that the quantity of free acid required to prevent the decomposition of a salt by water increases indefinitely with the proportion of salt contained in soln.; and that the decomposition of a dissolved salt increases or decreases with rise of temp. according as the decomposition is endothermal as in the case of antimony trichloride, or exothermal, as in the case of mercuric sulphate. If x represents the quantity of free acid, and y that of mercuric sulphate, $x^{1.58} = 4.7y$. Expressing the results in grams per 1000 grms. of water, there is:

15°	{ Free acid, SO_3	. . .	13.1	30.4	39.3	46.7	72.0	98.0
	{ HgSO_4	. . .	13.6	47.7	70.7	89.2	197.0	307.0
50°	{ Free acid, SO_3	. . .	8.7	14.0	32.0	41.0	48.0	63.5
	{ HgSO_4	. . .	4.9	9.0	28.9	46.6	53.2	68.0
100°	{ Free acid, SO_3	. . .	—	—	38.0	—	63.0	120.0
	{ HgSO_4	. . .	—	—	26.6	—	61.0	205.0

R. Varet also found the reaction to be endothermal; and in water acidified with sulphuric acid, the mercuric sulphate dissolves as an acid salt since with the precipitation 3.6 Cals. more heat are developed than is the case with any other oxysalt of mercury. J. Guinchant, however, believed that the soln. contains the normal salt, because the heat of soln. of mercuric sulphate is independent of the amount of the conc. of the acid, and because conc. sulphuric acid precipitates only the normal salt from acid soln. The fact that M. Geiseler found that a mol. of HgO requires the presence of 4 mols. of H_2SO_4 , or, according to R. Phillips, 5 mols. of H_2SO_4 , has led to the assumption that the soln. contains *mercuric hydrosulphate*, say, $\text{Hg}(\text{HSO}_4)_2$. There is no evidence of this. H. Eissfeldt always obtained the normal salt, from soln. in which the mol. ratio was as high as $\text{HgO} : \text{H}_2\text{SO}_4 = 1 : 5$. A. J. Cox estimated that the soln. must be at least 6.97N- H_2SO_4 at 25° , in order that the acid salt may be present. J. Kendall and A. W. Davidson found the f.p. of 0.023, 0.048, and 0.094 per cent. soln. of mercuric sulphate in sulphuric acid to be respectively 36° , 77° , and 127° , and the solid phase to be the normal sulphate.

H. Eissfeldt prepared colourless prismatic crystals of what he regarded as **mono-hydrated mercuric sulphate**, $\text{HgSO}_4 \cdot \text{H}_2\text{O}$, by leaving mercuric sulphate under a layer of cold water until it begins to turn yellow; but C. Hoitsema said that the basic sulphate $3\text{HgO} \cdot 2\text{SO}_3 \cdot 2\text{H}_2\text{O}$ is formed under these conditions. C. Hoitsema, however, did prepare the hydrate by leaving a sulphuric acid soln. of mercuric sulphate, Fig. 37, in a desiccator over sulphuric acid at room temp.

C. Hoitsema, and J. M. van Bemmelen studied the ternary system, $\text{HgO} - \text{SO}_3 - \text{H}_2\text{O}$, at 25° and 50° , and found that four solid phases, HgSO_4 , $\text{HgSO}_4 \cdot \text{H}_2\text{O}$, $\text{HgO} \cdot \text{HgSO}_4 \cdot 2\text{H}_2\text{O}$, and $2\text{HgO} \cdot \text{HgSO}_4$, may be present, after 3 hrs. agitation. At 25° , the first branch of the curve, Fig. 37, has $3\text{HgO} \cdot \text{SO}_3$ as solid phase as the mol. proportion of HgO increases from 0.33 to 2.0 per cent. and of SO_3 from 1.24 to 4.3 per cent. The curve then cuts another branch where the solid phase is $3\text{HgO} \cdot 2\text{SO}_3 \cdot 2\text{H}_2\text{O}$, and the mol. percentage of HgO increases but slightly with increasing content of acid. This curve then cuts that of the solid phase $\text{HgSO}_4 \cdot \text{H}_2\text{O}$ with 6.77 mols. per cent. of SO_3 and 2.02 mols. per cent. of HgO , and this phase persists until 8.1 mols. per

cent. of SO_3 and 0.6 mol. per cent. of HgO are present, Fig. 37, when the phase HgSO_4 appears. At 50° the phase $\text{HgSO}_4 \cdot \text{H}_2\text{O}$ disappears. The curves also indicate that soln. of turpeth mineral, and of mercuric sulphate as solid phase, will

FIG. 37.—The Ternary System, $\text{HgO}-\text{SO}_3-\text{H}_2\text{O}$.

precipitate the solid by warming, but this does not hold for cases in which the solid phase is $3\text{HgO} \cdot 2\text{SO}_3 \cdot 2\text{H}_2\text{O}$, where a rise of temp. may cause a transition to either $2\text{HgO} \cdot \text{HgSO}_4$ or to HgSO_4 ; this is a transition from $\text{HgSO}_4 \cdot \text{H}_2\text{O}$ to HgSO_4 . A line $0a$ equidistant from the two axes (on the same scale) does not cut the HgSO_4 curve; this means that HgSO_4 is not soluble in water without decomposition.

According to A. Ditte,⁴ mercuric sulphate is slightly soluble in **hydrofluoric acid**, but on evaporation, the soln. furnishes mercuric sulphate—there is no sign of the formation of a fluosulphate analogous to the chlorosulphate, $\text{HgSO}_4 \cdot 2\text{HCl}$. C. F. Mohr stated that mercuric sulphate does not absorb **hydrogen chloride** at ordinary temp., but when heated, it takes up that gas with avidity, much heat is developed, and some mercuric chloride is sublimed: $\text{HgSO}_4 + 2\text{HCl} \rightleftharpoons \text{HgCl}_2 + \text{H}_2\text{SO}_4$. The action is reversible so that some unchanged mercuric sulphate remains when the mercuric chloride has been all sublimed. R. J. Kane said that the dry salt absorbs hydrogen chloride, and gives it up again when warmed, when exposed to the air, or when washed with water. C. F. Mohr, and J. B. Hannay also found **hydrochloric acid** reacts with dry mercuric sulphate with a rise of temp. and the formation of mercuric chloride and sulphuric acid. A. B. Prescott found the reaction to be quantitative. According to A. Mailhe, and A. J. Cox, when a mixture of mercuric sulphate and **iodine** is heated there is a slight reaction, and a yellowish-white, hard, crystalline body is formed which is decomposed by water. E. Riegel, and A. Souville have studied the formation of **mercuric sulphatoiodide**, $\text{HgSO}_4 \cdot \text{HgI}_2$. According to K. Brückner, if a mixture of mercuric sulphate and iodine be mixed with water, it immediately becomes red owing to the formation of mercuric iodide—some mercuric iodate is also formed—the water extracts some mercurous and mercuric iodide and sulphate. M. Chateau believes that K. Brückner's sulphatoiodide is really an equilibrium mixture of a basic mercury sulphate, $\text{HgSO}_4 \cdot \text{HgO}$, and iodosulphate, $\text{HgSO}_4 \cdot \text{HgI}_2$, and the iodate, $\text{Hg}(\text{IO}_3)_2$, in the molar proportions 6:6:1. When the iodine is replaced by **bromine**, or **chlorine**, oxygen is evolved and mercuric bromide or chloride is formed. Mercuric sulphate is slightly soluble in **hydriodic acid**, and A. Ditte observed no sign of the formation of a compound analogous with $\text{HgSO}_4 \cdot 2\text{HCl}$; when the aq. soln. is evaporated, crystals of mercuric iodide appear. When triturated with potassium iodide, C. F. Mohr observed the formation of mercuric iodide and potassium sulphate.

According to A. Violi, when mercuric sulphate is mixed with molten **sulphur**, mercuric sulphide and sulphur dioxide are formed. For the action of **sulphuric acid**, *vide supra*. For silver mercuric sulphate and sulphato-chloride, see silver mercuric nitrate. J. L. Gay Lussac found that when heated with **carbon**—charcoal—mercury, carbon dioxide, and sulphur dioxide are formed. According to C. F. Mohr, **hydrogen cyanide** acts on heated mercuric sulphate, forming mercuric

cyanide and sulphuric acid, and R. Varet said the reaction is complete; according to C. F. Mohr, aq. **hydrocyanic acid** acts similarly and causes a rise of temp.; when the soln. is boiled, mercurous sulphate is deposited, and mercuric sulphate remains in soln. G. Denigès found that the **ethylene** hydrocarbons form a yellow precipitate in acid soln. J. Schröder found mercuric sulphate to be insoluble in **pyridine**; and A. Naumann, that it is likewise insoluble in **benzonitrile**. G. Denigès, C. Oppenheimer, etc., have noted the formation of complexes with a number of organic compounds—thiophene, aldehydes and ketones, etc.

The basic mercuric sulphates.—The hydrolytic action of water on mercuric sulphate and C. Hoitsema's work⁵ on the ternary system, $\text{HgO}—\text{SO}_3—\text{H}_2\text{O}$, have been previously discussed; the latter shows the existence of two well-defined basic salts at ordinary temp., $3\text{HgO}.\text{SO}_3$, and $3\text{HgO}.2\text{SO}_3.2\text{H}_2\text{O}$, and, according to W. Spring's scheme, these would be referred to the oxide, $(\text{HgO})_3$, and graphically represented:

The basic sulphates, $\text{HgO} : \text{SO}_3 = 1 : 3, 3 : 2$, and $3 : 1$, can also be formulated:

The basic sulphate, $3\text{HgO}.\text{SO}_3$, also called *turpeth mineral*, can be regarded as a salt of orthosulphuric acid, $\text{S}(\text{OH})_6$, or H_6SO_6 , namely, Hg_3SO_6 , *mercury orthosulphate*.

The results of A. J. Cox's application of the phase rule to systems of mercuric sulphate and dil. sulphuric acid are shown in Fig. 38, analogous with Fig. 36 (*q.v.*).

FIG. 38.—Basic Mercuric Sulphates (25°).

The ordinates represent mols of $(\text{Hg}_2, \text{Hg})\text{SO}_4$ per litre of soln., and the abscissæ the increase x in the basicity of the solid phase from $3\text{HgSO}_4—x\text{SO}_3$. Only one basic salt, $3\text{HgO}.\text{SO}_3$, was found corresponding with the minimum acid conc. 0.0013N- at 25°. The **mercuric dioxysulphate**, $3\text{HgO}.\text{SO}_3$, or $\text{HgSO}_4.2\text{HgO}$, has been long known as *mineral turpeth* or *turpeth*. It was studied by A. F. de Fourcroy, R. J. Kane, R. Phillips, M. Braamcamp and S. Oliva, etc. G. F. Hildebrandt, R. Phillips, A. J. Cox, A. Ditte, and R. Varet described its preparation by the action of water, particularly boiling water, on mercuric sulphate; and C. Hoitsema showed the conditions under which it is stable in dil. sulphuric acid. A. J. Cox showed that if mercuric oxide be shaken

some days with an excess of sulphuric acid, when all the mercuric oxide is converted into turpeth, the acid is between 6.87N- and 0.00065N-; and M. Geiseler obtained an orange-yellow mass resembling turpeth by heating 108 parts of mercuric oxide with 16.2 parts of sulphuric acid and 540 parts of water. M. Geiseler also made it by treating a warm soln. of mercuric nitrate with sodium sulphate. P. C. Ray obtained it by boiling the mother liquor remaining after the preparation of the hemihydrate. A. Mailhe prepared it by the action of mercuric sulphate on cupric hydroxide. W. R. Dunstan and T. S. Dymond prepared a yellow crystalline powder of **hemihydrated mercuric dioxysulphate**, $3\text{HgO}.\text{SO}_3.\frac{1}{2}\text{H}_2\text{O}$, or

$\text{HgSO}_4 \cdot 2\text{HgO} \cdot \frac{1}{2}\text{H}_2\text{O}$, from the mother liquids obtained in the preparation of mercuric oxynitrates. Although the yellow mineral turpeth is usually regarded as anhydrous, P. C. Ray said that this compound is the hemihydrate.

P. C. Ray showed that mercuric dioxysulphate may be formed as a lemon-yellow powder or in bright yellow scales; that obtained by the hydrolysis of mercuric sulphate consists of small, yellow tetragonal crystals. R. Watson gave 6.444 and L. Playfair and J. P. Joule 8.319 at 3.9° for the **specific gravity**. R. Watson, and E. J. Houston showed that the greenish-yellow powder becomes red when heated. According to G. F. Hildebrandt, when the anhydrous turpeth is heated it forms a white sublimate, and some mercury is obtained when it is rapidly and strongly heated. P. C. Ray found that when heated to 400° , the basic sulphate gives off mercury and oxygen, forming normal mercuric sulphate, which melts to a brown liquid and sublimes as mercurous sulphate with the evolution of oxygen and sulphur dioxide: $2(\text{HgSO}_4 \cdot 2\text{HgO}) = \text{Hg}_2\text{SO}_4 + 4\text{Hg} + 3\text{O}_2 + \text{SO}_2$. R. Varet gave for the **heat of formation**, $3\text{HgO} + \text{SO}_3 = 3\text{HgO} \cdot \text{SO}_3 + 50.58$ Cals., and 9.2 Cals. for the **heat of solution** in sulphuric acid, $3\text{HgO} \cdot \text{SO}_3 + 25\text{H}_2\text{SO}_4$. P. C. Ray also noted the change in the colour of the hemihydrate from yellow to red and brown when heated, and the restoration of the original colour on cooling. The water is, however, given off during the heating. A. Ditte said that the dioxysulphate is insoluble in **water**; A. F. de Fourcroy, that a litre of cold water dissolves 0.05 grm., and a litre of boiling water 1.67 grms.; and C. A. Cameron, that at 100° a litre of water dissolves 0.023 grm. of the dried and 0.031 grm. of the freshly precipitated sulphate. According to T. J. Pelouze, the action of **chlorine** is very slow at ordinary temp., and the result resembles that with mercuric oxide. A. Ditte said that the basic salt is soluble in dil. **hydrochloric acid**, which, according to C. F. Mohr, converts it completely into mercuric chloride and sulphuric acid. P. C. Ray said that the turbidity of the soln. in hydrochloric acid is due to the presence of traces of mercurous chloride. A. Vogel found that sulphurous acid dissolves turpeth, and the soln. becomes turbid owing to the separation of mercurous sulphate, and if the soln. be boiled, some mercury is formed. For H. le Chatelier, J. Guinchant, and R. Varet on the action of sulphuric acid, *vide supra*, Figs. 36-38. According to A. Ditte, if x denotes the weight of H_2SO_4 , and y that of mercuric oxide present in the form of $3\text{HgO} \cdot \text{SO}_3$, $y = 0.508x - 1.776$. P. C. Ray, and A. Ditte noted the solubility of the basic sulphate in dil. **nitric acid**, and also in **acetic acid**. M. Donovan said that the basic sulphate gives up all its acid to a soln. of **potassium hydroxide**.

C. Hoitsema prepared colourless, monoclinic plates of dihydrated **mercuric monoxysulphate**, $2\text{HgSO}_4 \cdot \text{HgO} \cdot 2\text{H}_2\text{O}$, or $3\text{HgO} \cdot 2\text{SO}_3 \cdot 2\text{H}_2\text{O}$, by the action of sulphuric acid on mercuric oxide; the conc. of the acid has been indicated previously—*vide supra*. Its presence was also indicated by the previous work of J. M. van Bemmelen. The air-dried compound loses water very slowly at 100° , but rapidly at 125° , forming an orange-yellow powder. The heat of soln. is probably negative. There is a doubt about the **mercuric monoxysulphate**, $2\text{HgO} \cdot \text{SO}_3$, or $\text{HgSO}_4 \cdot \text{HgO}$, reported by A. Mailhe to be formed by the action of nickel hydroxide or nickel carbonate on a soln. of mercuric sulphate. Similar remarks apply to the **mercuric monoxyltrisulphate**, $4\text{HgO} \cdot 3\text{SO}_3$, or $3\text{HgSO}_4 \cdot \text{HgO}$, reported by W. T. Hopkins, and N. Athanasesco—the former by the action of nitric acid on anhydrous turpeth, and the latter by heating a mixture of sodium sulphate with an acidified soln. of mercuric nitrate in a sealed tube at 250° . The dark yellow rhombohedral crystals are said to be decomposed by water with the separation of turpeth. C. Hoitsema regards it as a mixture of turpeth and mercuric sulphate.

The sulphobasic mercuric sulphates.—Some complexes of mercuric sulphide and sulphate have been reported—**mercuric sulphatosulphides**—with $\text{HgS} : \text{HgSO}_4$ in the mol. ratio 1 : 3, 1 : 2, 2 : 1, and 3 : 1, as well as some **mercuric oxysulphatosulphides**, $2\text{HgS} \cdot 3\text{HgSO}_4 \cdot \text{HgO} \cdot 4\text{H}_2\text{O}$, and $\text{HgS} \cdot \text{HgSO}_4 \cdot \text{HgO}$. W. Spring⁶ regards sulpho-sulphates as derivatives of

in which SO_4 -radicles may replace the sulphur radicles. Thus

The oxysulphates are similar, but here oxygen replaces sulphur. The yellow amorphous precipitate which H. W. F. Wackenroder obtained by adding mercurous nitrate to an aq. soln. of tetrathionic acid was shown by W. Spring to be **mercuric sulphatotrisulphide**, 3HgS.HgSO_4 , or $\text{Hg}_4\text{S}_4\text{O}_4$. The result is not satisfactory if the tetrathionic acid be poured into an aq. soln. of mercurous nitrate. Presumably mercurous tetrathionate, $\text{Hg}_2\text{S}_4\text{O}_6$, is first formed: $\text{Hg}_2\text{S}_4\text{O}_6 + \text{Hg}_2(\text{NO}_3)_2 = \text{Hg}_4\text{S}_4\text{O}_6 + 2\text{HNO}_3$; and immediately hydrolyzed by the water: $2\text{Hg}_2\text{S}_4\text{O}_6 + 3\text{H}_2\text{O} = \text{Hg}_4\text{S}_4\text{O}_4 + 2\text{H}_2\text{SO}_4 + \text{H}_2\text{SO}_3 + \text{S}$. The yellow precipitate was washed with carbon disulphide, and dried. N. Tarugi made the same compound by treating mercuric ethyl thiocarbonate, $\text{Hg}(\text{CH}_3\text{COS})_2$ with dil. sulphuric acid. According to W. Spring, the sp. gr. of the yellow powder at 20° is 6.4159, and the mol. vol., 154.6. It is stable up to 120° , but above that temp. it blackens, and decomposes, giving off white fumes. If the salt is contaminated with a little tetrathionic acid, it begins to decompose at about 50° . The purified salt is stable in light, but if contaminated with tetrathionic acid, it blackens, forming mercuric sulphide and sulphate. The salt is insoluble in water, but the yellow powder becomes darker in boiling water, and the filtrate is free from mercury, but contains sulphuric acid; the product remaining after treatment with boiling water is mercuric trioxysulphide, HgO.3HgS . Alkalies, iodides, and substances with an alkaline reaction, like the carbonates, form black mercuric sulphide, and this the more quickly the higher the temp. The salt is also blackened by hydrogen sulphide. It resists the action of acids excepting conc. tetrathionic acid, which partially dissolves it, and hot nitric acid converts it into HgS.3HgSO_4 . It is soluble in aqua regia, or a soln. of bromine in hydrochloric acid. When boiled with a soln. of barium nitrate it forms mercuric sulphide, barium sulphate, etc. The amount of heat evolved when this body is treated with sodium sulphide is taken to mean that it is not a mere mixture of mercuric sulphide and sulphate, but is rather a definite compound. When the sulphatotrisulphide is warmed to 95° – 100° with nitric acid of moderate conc., it forms **mercuric trisulphatosulphide**, HgS.3HgSO_4 , as a white powder, which is coloured yellow and then black by sodium hydroxide, and which is insoluble in acids and in aqua regia.

R. Palm reported the formation of white **mercuric disulphatosulphide**, HgS.2HgSO_4 , by mixing freshly precipitated mercuric sulphide in a conc. soln. of mercuric acetate with sulphuric acid or an alkali sulphate; and he added that a similar compound, but red in colour, is formed by the action of a warm soln. of mercuric sulphate on cinnabar. C. Barfoed also reported the formation of **mercuric sulphatodisulphide**, 2HgS.HgSO_4 , by the action of warm sulphuric acid on mercuric sulphonitrate. G. McP. Smith obtained this compound by the action of a sulphate on mercuric diperchloratosulphide.

H. Rose obtained a product, **mercuric oxysulphosulphate**, HgS.HgO.HgSO_4 , by treating an aq. soln. of mercuric sulphate with insufficient hydrogen sulphide for complete decomposition. The white precipitate becomes yellow by washing, and J. Jacobson said that it remains white if washed with cold water and dried in the water-bath, but if washed with boiling water it becomes yellow. According to K. Estrup, if a soln. of mercuric sulphate, made by dissolving 10 grms. of yellow mercuric oxide in 10 c.c. of conc. sulphuric acid and 40 c.c. of water, is shaken with one-fourth its vol. of carbon disulphide, and allowed to stand several weeks, white hexagonal plates are formed, which, after washing with dil. sulphuric acid, alcohol, and ether, have the composition $4\text{HgO.2HgS.3SO}_3.4\text{H}_2\text{O}$, or $2\text{HgS.HgO.3HgSO}_4.4\text{H}_2\text{O}$, or tetrahydrated **mercuric oxydisulphotrisulphate**, and he

gave the graphic formula $(\text{HO.Hg.SO}_4.\text{Hg.S.Hg})_2\text{SO}_4$. E. Bijlmann made it by dissolving 10 grms. of yellow mercuric oxide in 10 c.c. of conc. sulphuric acid mixed with 10 c.c. of water. When this compound is boiled with a soln. of potassium iodide, mercuric sulphide is precipitated and 2 eq. of alkali are set free. The compound is coloured yellow after standing some time in contact with water.

Mixed salts of mercuric sulphate.—C. Baskerville and F. W. Miller⁷ prepared a crystalline powder, which they regarded as **mercurous sulphate**, $\text{Hg}_2\text{SO}_4.\text{HgSO}_4$, by digesting mercury with conc. sulphuric acid for 2 hrs. at 150° . The precipitate is washed with 95 per cent. alcohol. T. Brooks obtained what he regarded as **mercurous oxysulphate**, $\text{Hg}_2\text{O.HgO.HgSO}_4$, or $\text{Hg}_2\text{O.2HgO.SO}_3$, by warming mercuromercuric nitrate with sodium sulphate. The product is insoluble in cold water, and it is decomposed by hydrochloric acid. There is nothing to show that these products are chemical individuals. Mercuric sulphate was found by C. Baskerville to form **mercuric hydrochlorosulphate**, $\text{HgSO}_4.\text{HCl}$, by evaporating to dryness a mixture of 20 grms. of mercuric sulphate and 20 c.c. of conc. hydrochloric acid, and then subliming the product at 240° . The sublimate is not attacked by hydrochloric acid, and but slightly by nitric acid. A. Ditte made **mercuric dihydrochlorosulphate**, $\text{HgSO}_4.2\text{HCl}$, by passing dry hydrogen chloride through a tube containing powdered mercuric sulphate at a temp. sufficient to volatilize any mercuric chloride which may be formed; also by evaporating a mixture of mercuric sulphate and hot conc. hydrochloric acid to dryness; and also by subliming a mixture of eq. proportions of mercuric sulphate and chloride. The white product is soluble in water without decomposition; it is soluble in hot sulphuric acid. C. Baskerville made monoclinic crystals of the hydrate, $\text{HgSO}_4.2\text{HCl.H}_2\text{O}$, by heating a mixture of eq. quantities of mercuric chloride and monohydrated mercuric sulphate. A. Ditte similarly prepared **mercuric dihydrobromosulphate**, $\text{HgSO}_4.2\text{HBr}$; but he could not obtain the corresponding compound with hydrogen iodide. A. Ditte also made white crystals of a basic salt, $\text{HgSO}_4.2\text{HgO.6HBr}$, by the action of dry hydrogen bromide on cooled mercuric oxysulphate, $\text{HgSO}_4.\text{HgO}$; and by evaporating to dryness a soln. of mercuric dioxysulphate, $\text{HgSO}_4.2\text{HgO}$, in hot hydrobromic acid. The compound decomposes when heated with water, forming mercuric bromide, and mercuric dihydrobromosulphate.

A. Ditte prepared white crystals of **mercuric dioxyhexahydrochlorosulphate**, $2\text{HgO.HgSO}_4.6\text{HCl}$, by the action of hydrogen chloride on turpeth mineral, and by evaporating to dryness a soln. of turpeth mineral in conc. hydrochloric acid. When heated the product is decomposed into water, mercuric chloride, and $\text{HgSO}_4.2\text{HCl}$. The corresponding **mercuric dioxyhexahydrobromosulphate**, $2\text{HgO.HgSO}_4.6\text{HBr}$, was prepared in a similar manner. According to A. Ditte, if a mixture of mercuric iodide and sulphuric acid be heated, sublimation begins at 200° , and iodine is given off; on cooling, a mass of crystals of a double salt is possibly formed. This product melts to a yellow liquid; it is coloured yellow and then red by cold water, and decomposed by hot water. A. Souville, and E. Riegel studied this reaction, and it has been assumed, without proof, that **mercuric iodosulphate**, $\text{HgSO}_4.\text{HgI}_2$, is formed. A. Ditte prepared white silky needles of **mercuric iodotrisulphate**, $\text{HgI}_2.3\text{HgSO}_4$, by heating mercuric iodide with fuming sulphuric acid, or, less readily, with ordinary sulphuric acid. The salt can be recrystallized from sulphuric acid; it melts to a yellow liquid which solidifies on cooling to a white fibrous mass; it is decomposed by water, forming mercuric iodide and turpeth mineral. A. Ditte also prepared five different double salts of mercuric sulphate and iodide by the action of sat. soln. of mercuric sulphate in sulphuric acid of different conc. upon mercuric iodide; **mercuric iodotetrasulphate**, $\text{HgI}_2.4\text{HgSO}_4.15$ or $18\text{H}_2\text{O}$, from a 41.1 per cent. sulphuric acid soln.; brilliant white needles of **mercuric oxyiodotrisulphate**, $\text{HgI}_2(3\text{HgO.2SO}_3)(\text{HgO.SO}_3).10\text{H}_2\text{O}$, or $\text{HgI}_2.\text{HgO.3HgSO}_4.10\text{H}_2\text{O}$, from 37.5 per cent. acid soln.; white nodular crystalline masses of **mercuric iododioxytetrasulphate**, $\text{HgI}_2.2(2\text{SO}_3.3\text{HgO}).10\text{H}_2\text{O}$, or $\text{HgI}_2.2\text{HgO.4HgSO}_4.10\text{H}_2\text{O}$, from 28.5 per cent. acid soln.; rose-coloured crystals of **mercuric**

diiodotrioxihexasulphate, $2\text{HgI}_2 \cdot 3(2\text{SO}_3 \cdot 3\text{HgO}) \cdot 10\text{H}_2\text{O}$, or $2\text{HgI}_2 \cdot 3\text{HgO} \cdot 6\text{HgSO}_4 \cdot 10\text{H}_2\text{O}$, from a 16.6 per cent. acid soln.; and white crystals of **mercuric iodoxydisulphate**, $\text{HgI}_2 \cdot (2\text{SO}_3 \cdot 3\text{HgO})$, or $\text{HgI}_2 \cdot \text{HgO} \cdot 2\text{HgSO}_4$, from a 9 per cent. acid soln. K. Brückner reported **mercuric hexaiodoiodatohexoxydodecasulphate**, $6\text{HgI}_2 \cdot 6(2\text{SO}_3 \cdot 3\text{HgO}) \cdot \text{Hg}(\text{IO}_3)_2$, or $6\text{HgI}_2 \cdot 6\text{HgO} \cdot 12\text{HgSO}_4 \cdot \text{Hg}(\text{IO}_3)_2$, by shaking together a mixture of 600 grms. of mercuric sulphate, 800 grms. of water, and 50 grms. of iodine; and by the action of an alcoholic soln. of potassium iodide on basic mercuric sulphate. The microcrystalline product is decomposed by water and dil. acids.

C. H. Hirzel⁸ prepared colourless monoclinic crystals of dihydrated **potassium trimercuric sulphate**, $\text{K}_2\text{SO}_4 \cdot 3\text{HgSO}_4 \cdot 2\text{H}_2\text{O}$, by dissolving a mol of mercuric sulphate in hot sulphuric acid, and adding potassium sulphate until the precipitate first formed re-dissolves. The soln. is treated with boiling water until a permanent turbidity is produced, and the whole is allowed to cool slowly. According to B. Finzi, when a boiling soln. of silver sulphate (sat. in the cold) is treated with yellow mercuric oxide until no more dissolves, and the filtered soln. allowed to stand a few days, pale-yellow rhombic tablets of **silver mercuric oxysulphate**, $\text{Ag}_2\text{SO}_4 \cdot \text{HgO}$, are deposited.

§ 31. Ammoniacal, Hydrazine, and Hydroxylamine Mercuric Sulphates

E. C. Franklin and C. A. Kraus¹ found mercuric sulphate to be insoluble in liquid ammonia; but it is soluble in aq. ammonia. N. A. E. Millon prepared a compound with the empirical formula $\text{Hg}_3\text{N}_2\text{H}_6\text{O}_2\text{SO}_4$, by saturating 90 c.c. of conc. and cold aq. ammonia with mercuric sulphate, and leaving the soln. in an atm. of ammonia over quicklime for some months. The prismatic crystals which formed were dried over sulphuric acid. L. Pesci was unable to prepare this sulphate, but obtained ammonia turpeth instead; N. A. E. Millon considered it to be *oxytrimercuridiammonium sulphate*, $3\text{HgO} \cdot \text{SO}_3 \cdot 2\text{NH}_3$; but E. C. Franklin regarded it as **mercuric diamminodioxysulphate**, $\text{Hg}(\text{NH}_3)_2\text{SO}_4 \cdot 2\text{HgO}$, or as *hydrated mercuriammonium mercurihydroxysulphatoamide*, $\text{NH}_2\text{Hg} \cdot \text{SO}_4 \cdot \text{HgNHHgOH} + \text{H}_2\text{O}$. N. A. E. Millon prepared prismatic crystals of what he regarded as *oxydimercuriammonium sulphate*, $2\text{HgO} \cdot \text{SO}_3 \cdot 2\text{NH}_3$, by evaporating a sat. soln. of mercuric sulphate in conc. aq. ammonia, in an atm. of ammonia. L. Pesci obtained only ammonia turpeth by following N. A. E. Millon's directions. E. C. Franklin regards this product as **mercuric diamminomonoxy sulphate**, $\text{Hg}(\text{NH}_3)_2\text{SO}_4 \cdot \text{HgO}$, or as *hydrated mercuriammonium sulphate*, $(\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot \text{H}_2\text{O}$.

N. A. E. Millon likewise prepared **mercuric diamminosulphate**, $\text{Hg}(\text{NH}_3)_2\text{SO}_4$, by saturating aq. ammonia with mercuric sulphate and evaporating to dryness over sulphuric acid. L. Pesci followed these directions and obtained a product of the same composition which he assumed to be a mixture. O. Schmieder prepared fine crystals of **monohydrated mercuric diamminosulphate**, $\text{Hg}(\text{NH}_3)_2\text{SO}_4 \cdot \text{H}_2\text{O}$, by evaporating a sat. soln. of precipitated mercuric oxide in a cold soln. of ammonium sulphate until a crop of crystals appeared; if the soln. be hot during the evaporation, a basic salt appears. L. Pesci followed O. Schmieder's directions, and obtained a compound of this same composition to which he assigned the formula $(\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot 3(\text{NH}_4)_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$. The crystals are stable in air, and, according to L. Pesci, rapidly become opaque when confined over sulphuric acid. The compound is white at 90° , but at 115° it becomes reddish and loses all its water. When heated in a glass tube, water and ammonia are first evolved; mercury and a yellow sublimate then appear—the latter is white when cold—the reddish-brown residue melts with bubbling and evolution of sulphur dioxide; and at a still higher temp., all is volatilized. According to O. Schmieder, when the compound is treated with a very small proportion of cold water, a complex compound which L. Pesci symbolized $(\text{NH}_4)_2\text{SO}_4 \cdot 7(\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$ —*vide infra*—is formed; and with boiling water ammonia turpeth—*vide infra*—appears. A soln. of potassium hydroxide furnishes a basic salt and ammonia even at ordinary temp., and with a boiling soln., the yellow compound first produced is gradually converted into mercuric oxide. The compound is easily soluble in aq. soln. of ammonium sulphate

or ammonium chloride; in dil. or conc. hydrochloric acid; and in very dil. nitric or sulphuric acid; but it is not soluble in conc. nitric acid, and conc. sulphuric acid decomposes it, forming mercuric and ammonium sulphates. Hydrogen sulphide converts it completely into mercuric sulphide and ammonium sulphate.

K. A. Hofmann and E. C. Marburg obtained a pulverulent precipitate of **mercuric hydrazinosulphate**, $\text{HgSO}_4 \cdot \text{N}_2\text{H}_4$, by adding hydrazine sulphate to a soln. of mercuric nitrate. M. Adams made **mercuric dihydroxylaminosulphate**, $\text{HgSO}_4 \cdot 2\text{NH}_2\text{OH} \cdot \text{H}_2\text{O}$, by shaking freshly precipitated mercuric oxide, or dry mercuric sulphate with a cold 10 per cent. soln. of hydroxylamine sulphate. An excess of mercuric oxide is to be avoided. The crystals are repeatedly washed with water, and dried over phosphorus pentoxide. The compound is stable in darkness, but changes colour in light. It decomposes rapidly at 55° ; and it is decomposed by cold water, being coloured first reddish-yellow, and finally black. It is stable under water containing some sulphuric acid or hydroxylamine sulphate.

A. F. de Fourcroy² found that soln. of a mercuric sulphate—not the nitrate or chloride—give a white precipitate with ammonium sulphate. G. C. Wittstein stated that a soln. of mercuric oxide in a cold aq. soln. of ammonium sulphate is not precipitated by aq. ammonia; and he added that if mercurous oxide be used, heat is necessary for the dissolution and some mercury is precipitated. C. H. Hirzel dissolved a mol of mercuric sulphate in hot sulphuric acid, and added a mol of ammonium sulphate; the precipitate first formed redissolved, boiling water was added, and the mixture cooled slowly when monoclinic prisms of **dihydrated ammonium trimeric sulphate**, $(\text{NH}_4)_2\text{SO}_4 \cdot 3\text{HgSO}_4 \cdot 2\text{H}_2\text{O}$, separated out. The double salt is much dissociated in aq. soln. since H. C. Jones and K. Ota found that the conductivity very nearly corresponds with the value calculated from that of the single salts.

C. Kosmann prepared what he regarded as **mercuric ammonium sulphatochloride**, $2\text{HgSO}_4 \cdot \text{HgCl}_2 \cdot 2\text{NH}_4\text{Cl}$, by boiling mercuric chloroamide, NH_2HgCl , with sufficient water, acidulated with sulphuric acid, for complete soln. The liquid is evaporated on a water-bath for crystallization: $4\text{NH}_2\text{HgCl} + 4\text{H}_2\text{SO}_4 = \text{HgSO}_4 + (\text{NH}_4)_2\text{SO}_4 + 2\text{NH}_4\text{Cl} \cdot 2\text{HgSO}_4 \cdot \text{HgCl}_2$. The crystals are dried by press. between filter-paper. They are decomposed by water; potassium hydroxide liberates ammonia; and ether extracts mercuric chloride.

P. C. Ray obtained a white crystalline powder of **monohydrated dimercuriammonium sulphate**, $(\text{NHg}_2)_2\text{SO}_4 \cdot \text{H}_2\text{O}$, by heating dimercuriammonium nitrite with dil. sulphuric acid slowly up to the b.p. The product is soluble in hydrochloric acid. By warming Millon's base with dil. sulphuric acid, C. F. Rammelsberg, and L. Pesci obtained **dihydrated dimercuriammonium sulphate**, $(\text{NHg}_2)_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, as a pale yellow powder, and L. Pesci obtained octahedral crystals by adding mercuric sulphate to 70–100 c.c. of cold conc. aq. ammonia until no more dissolved, and evaporating the soln. for crystals. L. Pesci prepared a double salt, **dodecahydrated ammonium heptadimercuriammonium sulphate**, $(\text{NH}_4)_2\text{SO}_4 \cdot 7(\text{NHg}_2)_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$, which some regard as mercuriammonium oxydimercuriammonium sulphate, *q.v.* This salt becomes anhydrous when heated to 115° . H. Saha and K. N. Choudhuri obtained **dihydrated mercuriammonium oxysulphate**, $2\text{HgO} \cdot (\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, by dissolving mercurous sulphate in aq. ammonia, and evaporating the filtered soln. over conc. sulphuric acid.

Prismatic crystals of another ammonium dimercuriammonium sulphate, $14(\text{NH}_4)_2\text{SO}_4 \cdot 5(\text{NHg}_2)_2\text{SO}_4 \cdot 16\text{H}_2\text{O}$, were prepared by L. Pesci by adding mercuric sulphate to aq. ammonia of sp. gr. 0.906 until no more dissolved; mixing the filtered soln. with an equal vol. of an aq. soln. of ammonia sat. at 0° ; and allowing the mixture to stand 24 hrs. This salt becomes anhydrous at 115° – 125° . It loses ammonium sulphate when treated with cold water, and forms $(\text{NH}_4)_2\text{SO}_4 \cdot 7(\text{NHg}_2)_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$, and finally the sulphate of Millon's base. The salt is soluble in aq. ammonia. The aq. soln. gives a precipitate of mercuric sulphide when treated with hydrogen sulphide, and a neutral soln. of ammonium sulphate remains. E. C. Franklin rearranges the symbols in the formula of the hydrate so as to form $\text{HgO} \cdot 19\frac{1}{2}(\text{HgSO}_4 \cdot (\text{NH}_3)_2) \cdot 15\text{H}_2\text{O}$; he regards L. Pesci's compound as a partially dehydrated slightly basic specimen of monohydrated mercuric diamminosulphate. Monohydrated mercuric diamminosulphate, $\text{HgSO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$ —*vide supra*—was regarded by

L. Pesci as an ammonium dimercuriammonium sulphate: $3(\text{NH}_4)_2\text{SO}_4 \cdot (\text{NHg}_2)_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$. The basic sulphate of Millon's base, $\text{Hg}(\text{OH})_2 \cdot (\text{NHg}_2)_2\text{SO}_4 \cdot (\text{NH}_4)_2(\text{NHg}_2)_2\text{SO}_4$, was prepared by C. F. Rammelsberg as a pale yellow powder by the action of a hot soln. of ammonium sulphate on freshly precipitated mercuric oxide.

A. F. de Fourcroy, and R. J. Kane treated mercuric sulphate with aq. ammonia, and found a yellow basic sulphate is first produced, and this is gradually transformed into a white powder. The reaction is the same if the liquid is boiling, but it then proceeds faster. This compound is the so-called *ammonia turpeth*. According to the analyses of R. J. Kane, N. A. E. Millon, C. H. Hirzel, and O. Schmieder, the composition corresponds with $\text{Hg}_4\text{N}_2\text{H}_4\text{O}_2 \cdot \text{SO}_4$, while P. C. Ray gave $\text{Hg}_4\text{N}_2\text{H}_2\text{O} \cdot \text{SO}_4$, but without analyses. The constitution can be represented as an *oxydimercuriammonium sulphate*, $\{\text{NH}_2(\text{HgOHg})\}_2\text{SO}_4$. E. C. Franklin regards it as a mixed hydroxy-amminio basic sulphate of mercury, and represents the analyses by $(\text{HO.Hg.NH.Hg})_2\text{SO}_4$, or the *sulphate of Millon's base*, or **mercuric hydroxysulphatoamide**.

Ammonia turpeth is formed by the action of dil. sulphuric acid on Millon's base, $(\text{HO.Hg})_2 \cdot \text{NH}_2\text{OH}$, or on the hydroammonio base, $\text{Hg} : \text{N.Hg.OH}$. It is also made by the action of aqua ammonia on the basic sulphate $2\text{HgO.Hg}_2\text{SO}_4$; C. Ullgren prepared it by the action of a soln. of ammonium sulphate on the basic sulphate; C. H. Hirzel, by the action of a soln. of ammonium sulphate on mercuric oxide; N. A. E. Millon, by diluting with water a soln. of mercuric sulphate in conc. aq. ammonia; and O. Schmieder, by the action of boiling water on hydrated mercuric diamminosulphate, $\text{HgSO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$. C. Ullgren's and O. Schmieder's products had a yellowish tinge, while those of R. J. Kane, and C. H. Hirzel were white. The white powder obtained by N. A. E. Millon was crystalline, L. Playfair and J. P. Joule gave 7.319 for the sp. gr. at 3.9° . O. Schmieder said that it is not decomposed at 115° ; and R. J. Kane, that it turns brown when heated, giving off water, nitrogen, a trace of ammonia, and, according to O. Schmieder, and C. H. Hirzel, a little mercury, leaving behind mercurous sulphate. C. H. Hirzel also obtained some sulphur dioxide. According to C. Ullgren, and R. J. Kane, ammonia turpeth is sparingly soluble in water, and it is soluble in hydrochloric and nitric acids, giving off nitrous fumes— N_2O_3 ; the aq. soln. contains ammonia. C. H. Hirzel, and O. Schmieder found it to be insoluble in nitric acid; and the former said that it is soluble in conc. sulphuric acid, forming ammonium mercuric sulphate, $(\text{NH}_4)_2\text{SO}_4 \cdot 3\text{HgSO}_4 \cdot 2\text{H}_2\text{O}$; O. Schmieder, however, said that it is insoluble in conc. sulphuric acid, but readily soluble in the dil. acid. C. H. Hirzel found that it is soluble in a soln. of ammonium sulphate, and, added O. Schmieder, without the evolution of ammonia; O. Schmieder also found that it is soluble in a boiling soln. of ammonium chloride with the copious evolution of ammonia. R. J. Kane found that when hydrogen sulphide is passed into water with the powder in suspension, mercuric sulphide and a neutral soln. of ammonium sulphate are formed. C. Ullgren found no ammonia is evolved when it is treated with a soln. of potassium hydroxide; but with a prolonged boiling, C. H. Hirzel obtained a little ammonia and a yellow product—O. Schmieder said yellow mercuric oxide is the ultimate product of this action. C. Ullgren obtained ammonia by treating the compound with potassium sulphide.

O. Schmieder obtained a product with the empirical composition $\text{Hg}_7\text{N}_4\text{H}_8\text{O}_3 \cdot 2\text{SO}_4$, by the action of cold water on $\text{HgSO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$, or by pouring a soln. of ammonium sulphate, sat. with mercuric oxide, into cold water. L. Pesci also made a compound with the same composition by a similar process, and also by the action of hot dil. nitric acid on his ammonium dimercuriammonium sulphate. This compound can be regarded as *mercuriammonium oxydimercuriammonium sulphate*, $(\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot 3(\text{NH}_2\text{HgOHg})_2\text{SO}_4$; or, according to L. Pesci, $(\text{NH}_4)_2\text{SO}_4 \cdot 7(\text{NHg}_2)_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$, i.e. *dodecahydrated ammonium dimercuriammonium sulphate*; or, according to E. C. Franklin, $(\text{NH}_2\text{Hg})_2\text{SO}_4 \cdot 3(\text{HOHg.NHHg})_2\text{SO}_4$, i.e. **mercuriammonium hydroxyamidodisulphate**. L. Pesci found that a mol. of the heavy white earthy powder loses three mols. of water when heated to 115° , and furnishes

$\text{Hg}_7\text{N}_2\text{H}_4\text{O}_2\cdot\text{SO}_4$, or, according to E. C. Franklin, $(\text{NH}_2\text{Hg})_2\text{SO}_4\cdot 3(\text{Hg}_2\text{N})_2\text{SO}_4$, i.e. **mercuriammonium dimercuriammonium sulphate**. O. Schmieder found that when heated in a closed tube, mercuriammonium hydroxyamid sulphate turns brown, gives off water, nitrogen, and mercury, and on cooling, white mercurous sulphate remains; when washed with boiling water, ammonium sulphate is extracted—according to L. Pesci, ammonia turpeth is formed. O. Schmieder found that a boiling dil. soln. of potassium hydroxide gradually converts it into mercuric oxide, and that a conc. soln. of ammonium sulphate converts it into $\text{HgSO}_4\cdot 2\text{NH}_3\cdot \text{H}_2\text{O}$. A boiling soln. of ammonium chloride dissolves the salt completely with the evolution of ammonia. It is readily soluble in conc. and dil. hydrochloric acid, or in very dil. sulphuric acid, while it is not soluble in conc. sulphuric acid or in conc. or dil. nitric acid.

O. Schmieder prepared a product with the composition $\text{Hg}_5\text{N}_2\text{H}_4\text{SO}_4$, by dissolving $\text{HgSO}_4\cdot 2\text{NH}_3\cdot 2\text{H}_2\text{O}$ in dil. sulphuric acid; pouring the soln. into an excess of a dil. soln. of potassium hydroxide; and washing the precipitate with warm water. L. Pesci followed O. Schmieder's directions but failed to get this compound, and obtained instead ammonia turpeth. O. Schmieder regarded it as *oxydimercuriammonium oxytrimercuriammonium sulphate*, $\{\text{NH}_2(\text{HgOHg})\}\cdot\{\text{NH}_2(\text{HgOHgOHg})\}\text{SO}_4$; and E. C. Franklin regarded it as **mercuric hydroxy-amido-oxysulphate**, $(\text{HOHgNHg})_2\text{SO}_4\cdot \text{HgO}$. O. Schmieder said that the white powder becomes yellowish-white at 115° without loss of weight, and when heated in a tube, it gives off water, mercury, and nitrous fumes; the reddish-brown sintered mass becomes white when cooled; if heated to a still higher temp. it melts, and bubbles with the evolution of sulphur dioxide; and if heated still more, all is volatilized. When boiled with a dil. soln. of potassium hydroxide, ammonia is evolved and the mass acquires a yellow colour; by the prolonged action of a conc. soln. of potassium hydroxide, the ultimate product is mercuric oxide; it is completely soluble in a boiling soln. of ammonium chloride with the evolution of ammonia; but it dissolves in a boiling soln. of ammonium sulphate without the evolution of ammonia. It is soluble in dil. and conc. hydrochloric acid, and in very dil. sulphuric acid; but insoluble in nitric acid and conc. sulphuric acid.

§ 32. The Mercury Carbonates

In his essay *De acido aëreo* (Upsala, 1774), T. Bergmann obtained mercury carbonate by treating a soln. of mercury in an acid with an alkali carbonate. According to P. N. Raikow,¹ carbon dioxide has no action on mercurous oxide. H. Demarçay found that when a soln. of a mercurous salt is treated with potassium or sodium carbonate, a dirty white precipitate is formed; the corresponding hydrocarbonates give a white precipitate which becomes black when the liquid is boiled; and

ammonium carbonate gives a grey or black precipitate. According to C. Arnold, the precipitate produced by the addition of a soln. of alkali carbonate, ammonia, or potassium hydroxide to a mercurous salt soln. is not soluble in a sat. soln. of potassium carbonate, nor in a sat. soln. of ammonium carbonate in water or in 10 per cent. aq. ammonia. A. P. Castanares found that unlike bismuth salts, hot soln. of mercury salts, acidified with nitric acid, are not precipitated by ammonium carbonate. H. Rose obtained a reddish-brown oxychloride by adding alkali carbonate to a soln. of mercuric nitrate; and K. Thümmel showed that when the alkali carbonate is added to a soln. of mercuric chloride, the oxychloride is precipitated, but if a soln. of mercuric chloride be added to one of the alkali carbonates, mercuric oxide is precipitated. D. Vitali, however, obtained no precipitation with a soln. of mercuric cyanide. If an ammonium salt be present, the alkali carbonates gives a white precipitate; and if organic substances—sugar, gum, etc.—are present, a black precipitate is produced in a dil. soln. of a mercuric salt, and in conc. soln. a dirty yellow precipitate which becomes black in a few hours, or immediately on boiling.

According to R. Schindler, and E. Biltz, soln. of potassium or sodium hydrocarbonate give a reddish-brown precipitate when added to soln. of mercuric sulphate or nitrate; and with an eq. amount of a soln. of mercuric chloride, a white turbidity appears which becomes reddish, and finally precipitates a reddish oxychloride—part of the mercury remains in soln. According to A. Barthélemy, the yellow precipitate produced by an alkali hydrocarbonate in a soln. of mercurous nitrate is soluble in an excess of the latter. H. Vittenet noted that natural waters containing hydrocarbonates in soln. give a precipitate with a 10 per cent. soln. of mercuric and ammonium chlorides. H. Demarçay found mercurous salt soln. are precipitated in the cold by magnesium carbonate, or by the alkaline earth carbonates, and H. Rose found that the precipitate is a mixture of mercuric oxide and the metal, not mercurous oxide, when barium carbonate is used, and that the precipitation is quantitative with mercuric sulphate or nitrate, but, even with boiling soln., mercuric chloride is not precipitated. E. Biltz thought that soln. in which there are 20 mols of sodium hydrocarbonate, or 45 mols of potassium hydrocarbonate, to one of mercuric chloride, contain a double salt of alkali hydrocarbonate and mercuric carbonate; but K. Thümmel objected that mercuric carbonate is not produced from soln. of mercuric chloride—the mixed soln. gives off carbon dioxide.

More or less impure **mercurous carbonate**, Hg_2CO_3 , is precipitated as a yellow powder when a soln. of mercurous nitrate is mixed with sodium or potassium carbonate; and in order to get the salt quite sat. with carbon dioxide, J. Setterberg recommended mixing the nitrate with a slight excess of potassium hydrocarbonate and allowing the mixture to stand for a few days. The mixture is frequently agitated to ensure the decomposition of any basic mercuric nitrate which may have been precipitated. The precipitate is then quickly washed, and dried in vacuo over conc. sulphuric acid. H. Rose triturated crystalline mercurous nitrate with potassium hydrocarbonate and water, and washed the product as rapidly as possible. J. Lefort recommended dropping the mercurous nitrate soln. into a cold sat. soln. of potassium hydrocarbonate, washing with carbonic acid, and drying in darkness over sulphuric acid.

According to J. Lefort, the pale yellow powder does not amalgamate gold, showing the absence of free mercury—but if the powder has been exposed to light, the gold is quickly amalgamated. L. J. Proust found that the salt is converted into mercuric oxide and mercury when exposed to air; some carbon dioxide is also given off. G. C. Wittstein stated that this decomposition readily occurs under warm water, and H. Rose that it is very rapid in boiling water. C. H. Pfaff added that if mercurous carbonate retains some alkali carbonate, employed as precipitant, the latter abstracts some carbon dioxide and the product turns black. J. Lefort found that the dried carbonate loses carbon dioxide at 130° , and forms mercuric oxide and mercury. G. C. Wittstein found that mercurous carbonate is blackened by aq.

ammonia, and some is dissolved with the separation of mercury; the soln. deposits a white powder when exposed to the air, and on evaporation leaves a compound of ammonia and mercuric oxide. O. Hermes found a small trace of thiocyanic acid precipitates mercury.

According to P. N. Raikow, when carbon dioxide is passed into a mixture obtained by adding to a *N*-soln. of mercuric chloride, a quantity of potassium hydroxide sufficient to convert about one-fifth of the metal into hydroxide, the mercuric oxide is converted into normal **mercuric carbonate**, HgCO_3 , mixed with a little acid carbonate. W. Leuze prepared **colloidal mercuric carbonate** by adding a dil. soln. of sodium carbonate to a dil. soln. of mercuric chloride and sodium protalbinat or lysalbinat. The soln. may be dialyzed.

N. A. E. Millon dropped a soln. of mercuric nitrate into a large excess of a soln. of potassium or sodium carbonate, and obtained an ochre-yellow powder, **mercuric trioxycarbonate**, $\text{HgCO}_3 \cdot 3\text{HgO}$, or $4\text{HgO} \cdot \text{CO}_2$. He also showed that if the alkali carbonate soln. be added to that of mercuric nitrate, as recommended by R. Phillips, the precipitate may be contaminated with some nitrate. The precipitate should be washed with cold water, and it can be dried at 130° without decomposition. Yellow mercuric oxide is formed when the product is treated with a soln. of potassium hydroxide. If potassium hydrocarbonate be employed as precipitant, N. A. E. Millon, and J. Setterberg obtained mercuric dioxycarbonate, $\text{HgCO}_3 \cdot 2\text{HgO}$, or $3\text{HgO} \cdot \text{CO}_2$. If a mixture of the mercuric salt and alkali hydrocarbonate be boiled, the precipitate contains scarcely a trace of carbon dioxide. According to K. Thümmel, when an alkali carbonate or hydrocarbonate is added to a soln. of mercuric nitrate, a white precipitate of basic nitrate, $2\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2$, is formed, and it is this, not the mercuric nitrate in soln., which forms $2\text{HgO} \cdot \text{HgCO}_3$. According to G. C. Wittstein, and R. H. Brett, the brownish-red basic carbonate is slightly soluble in carbonic acid, or in a soln. of potassium carbonate, or ammonium chloride. W. C. Reynolds claimed to have made *potassium mercuric carbonate*, but "not crystalline or of definite composition"; and A. Ferraro, an unstable *calcium mercuric carbonate* by adding mercuric chloride to calcareous waters free from ammonia.

C. F. Rammelsberg "boiled Millon's base with a soln. of sodium carbonate and dried the yellow product in a steam oven; the analysis corresponded with $\text{Hg}_4\text{N}_2\text{H}_4\text{O}_2\text{CO}_3$, and he represents it as *dimercuriammonium carbonate*, $(\text{NHg})_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$, while E. C. Franklin represents it as **mercuric hydroxyamido-carbonate**, $(\text{HOHgNHHg})_2\text{CO}_3$. L. Pesci stated that it reacts vigorously with a soln. of ammonium bromide. N. A. E. Millon passed carbon dioxide through water in which Millon's base was suspended, or treated Millon's base with a soln. of ammonium carbonate or potassium hydrocarbonate, and obtained what he regarded as oxydimercuriammonium carbonate, $\{\text{NH}_2(\text{HgOHg})\}_2\text{CO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, but E. C. Franklin regarded it as a hemihydrate, $(\text{HOHgNHHg})_2\text{CO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$. C. H. Hirzel obtained the same product by boiling a soln. of ammonium carbonate in contact with mercuric oxide; F. Seemann preferred an ammoniacal soln. of ammonium carbonate. According to C. H. Hirzel, the product is a yellow powder which gradually becomes grey on exposure to light. The dried carbonate does not lose water at 130° , but at 145° , 1.01 to 1.80 per cent. of water is given off, and at 180° – 200° more water and ammonia are evolved. F. Seemann found that a litre of water dissolves 0.003 grm. of the salt. It is decomposed by conc. hydrochloric acid, forming NH_2HgCl ; with a boiling soln. of potassium hydroxide no ammonia is given off; with a soln. of potassium iodide or sulphide, the whole of the nitrogen is given off as ammonia; conc. nitric acid reacts vigorously, forming nitrates; sulphuric acid has scarcely any action in the cold, but when boiling, sulphates are gradually formed; and with a soln. of sodium silicate, the silica is all precipitated. C. H. Hirzel digested mercuric oxide with a cold soln. of ammonium carbonate, and obtained a monohydrated form of this carbonate as a snow-white powder which turns grey in light and reacts like the hemihydrate. These three compounds, said E. C. Franklin, "cannot be essentially different."

§ 33. Arrested Reactions

There is a number of reactions which give different products according to the mode of mixing the reacting constituents. Thus, C. F. Gerhardt¹ found that if a neutral soln. of lead nitrate be added to a soln. of sodium phosphate in excess, a flocculent precipitate of normal lead phosphate, $Pb_3(PO_4)_2$, is obtained: on the other hand, if the sodium phosphate soln. be added to the lead nitrate soln. in excess, monoclinic crystals of a lead nitratophosphate, say, $Pb_2(NO_3)PO_4$, are obtained. The former precipitate becomes anhydrous at 100° , the latter requires a much higher temp. to drive off the water. With copper sulphate and potassium hydroxide a green basic copper sulphate, $nCu(OH)_2 \cdot mCuSO_4$, is precipitated when the latter is added to an excess of the former; and blue copper hydroxide, $Cu(OH)_2$, when the admixture is made in the inverse manner. K. Thümmel noted that alkali carbonate soln. added to mercuric chloride soln. gives mercuric oxychloride, while if the soln. be mixed in the reverse order, mercuric oxide is precipitated; J. Messner, that when potassium ferrocyanide is poured into an excess of a soln. of copper sulphate, the precipitated potassium copper ferrocyanide has less potassium than if the soln. be mixed in the reverse order; F. Raschig, that the colour reaction between aniline and sodium hypochlorite is or is not obtained according as ammonia is added before or after the two soln. are mixed; and J. Sperber, that when hydriodic acid is added to hydrogen peroxide, a colourless liquid is obtained, but when the mixing is done in the reverse order, there is a separation of iodine. In analytical work, also, the composition of the precipitate may depend on the way the soln. are mixed; thus G. A. Hulett and L. H. Duschak, and G. McP. Smith found this to be the case with barium sulphate precipitated from acid soln. of barium chloride; and E. G. Beckett, with antimony sulphide precipitated from acid soln. of antimony chloride.

The phase rule would say that equilibrium is not attained in these reactions, and that the state of equilibrium is attained more nearly by one method of mixing than in another; and that once a precipitate has been formed the time required for the subsequent progress of the reaction may be so slow that the composition of the precipitates appear permanently different. The phase rule, however, assumes that an indefinitely long time is available. The observed fact is that the products of some reactions are determined by the mode of mixing. C. L. Berthollet said:

The faculty of combining more quickly with one substance than with another sometimes produces precipitations which may be considered as accidental, and which do not take place if the circumstances render the action slower. T. Bergman observed that when conc. sulphuric acid was poured into a sat. soln. of potassium sulphate, alum, ferrous sulphate, mercuric chloride, or other salts which water dissolves with difficulty, the salts were

rapidly precipitated; but if the sulphuric acid was poured in by small portions and the liquid agitated, these precipitations did not take place. The same phenomenon is observed on suddenly mixing an aq. soln. of barium chloride with conc. hydrochloric acid, and in a great number of other circumstances in which it is seen that a precipitate is formed at the first instant of the mixture, and afterwards redissolved slowly or more quickly by the assistance of heat or of agitation.

If the reaction be arrested while in progress, the mode of mixing is of vital importance in order to obtain particular products, because the final state of equilibrium may be attained by different paths by the different modes of mixing. This is still more the case in reactions between mixtures of powdered solids. Even with liquids it is by no means easy to get a homogeneous mixture in a short time by agitation. Thus, C. L. Berthollet said:

Although sulphuric acid exercises a brisk action on water and retains it strongly, nevertheless, it is difficult to bring it to a uniform soln. so that when the liquor is interposed between the eye and the light it shall not appear striated. It is the same with alcohol.

Similarly with molten glass for optical purposes, in spite of the fact that the molten glass is stirred for many hours, it is very difficult to manufacture large pieces free from striæ. There are numerous industries—e.g. cement, lime, plaster of Paris, annealed metals, pottery (*q.v.*), etc.—in which success or failure depends on the arresting of reactions at precisely the right stage; and this, in turn, often depends on differences in the modes of mixing; and on differences in the nature of the components employed to furnish a product with the same ultimate composition.

According to F. Auerbach and H. Pick, even the state of equilibrium of the reaction between lead chromate and sodium carbonate is determined by the mode of mixing the reacting constituents. They showed that the state of equilibrium: $2\text{PbCrO}_4 + 2\text{Na}_2\text{CO}_3 + \text{H}_2\text{O} \rightleftharpoons \text{PbO} \cdot \text{PbCrO}_4 + 2\text{NaHCO}_3 + \text{Na}_2\text{CrO}_4$, is not the same when the start is made from different sides; although it is not unlikely that if an indefinitely long time were available, the same end-state would be attained. A precipitate may have more time to change into a polymeric, less reactive form when obtained by one process than by another process, and this secondary reaction might make it appear that the products are different when obtained in different ways. The reaction $\text{PbCO}_3 \rightleftharpoons \text{PbO} + \text{CO}_2$, is not reversible like the corresponding reaction $\text{CaCO}_3 \rightleftharpoons \text{CaO} + \text{CO}_2$, because the lead oxide immediately changes into a less reactive form; if water vapour be present, the lead oxide does not change so rapidly and the reaction is then reversible. Again, P. P. von Weimarn showed that the physical character of precipitates is largely determined by the conditions under which the precipitating salts interact; F. J. Otto, that precipitated gold is finer when obtained by pouring ferrous chloride into a soln. of gold chloride, than when the latter is poured into the former; and J. L. Gay Lussac, that the tint of purple of Cassius is determined by the rapidity of admixture.

§ 34. Mercurous Nitrate

Mercury nitrate was known to the mediæval alchemists. It is mentioned by A. Libavius,¹ Basil Valentine, etc. T. Bergman distinguished the variety prepared with cold nitric acid from that prepared with hot nitric acid, and this was

later shown to depend on the existence of higher and lower states of oxidation, the former corresponding with mercuric nitrate, $\text{Hg}(\text{NO}_3)_2$, where mercury is bivalent, and the latter with mercurous nitrate, HgNO_3 , where mercury is univalent—*vide supra*. There are also several basic nitrates. In 1806, A. F. de Fourcroy and L. J. Thénard said that black and red mercury oxides each *se combinerait en trois proportions différentes à l'acide azotique*.

Short prismatic crystals of **mercurous nitrate**, HgNO_3 , were obtained by C. G. Mitscherlich² by leaving cold dil. nitric acid upon an excess of mercury. According to W. Reuss, in the action of cold dil. nitric acid on mercury, only the normal salt is produced whether the acid or the mercury is in excess, for these only affect the water of crystallization of the resulting salt. A low temp. and dil. acid favour the formation of crystals with a large proportion of water of crystallization. If the mercury and acid be heated on the water-bath, the normal salt is alone produced. The effects of an excess of the acid or mercury are the same provided that the proportion of free acid does not fall below 4–5 per cent. nor rise above 15–20 per cent. If the conc. of the free acid be smaller than 4–5 per cent., a basic salt will be formed, and if higher than 15–20 per cent., a mercuric salt will be produced. If the crystals are left in the soln. for a long time, C. G. Mitscherlich, and J. A. W. Büchner observed that crystals of a basic nitrate are formed. This reaction no doubt depends on the conc. of the free acid in the soln. P. C. Ray recommended using an acid with a sp. gr. between 1.135 and 1.140; J. Lefort, nitric acid of sp. gr. 1.42 diluted with 1–2 times its vol. of water; and J. C. G. de Marignac, nitric acid diluted with 2–3 times its vol. of water. N. A. E. Millon, W. J. Russell, and V. H. Veley regard mercurous nitrate as a secondary product of the action of nitric acid on mercury; E. Divers, as a primary product—*vide action* of nitric acid on mercury. C. F. Bucholz dissolved mercury in moderately conc. nitric acid, evaporated the soln. to dryness, triturated the residue with mercury and water in a hot mortar until the fluidity of the metal is destroyed, dissolved the mass in hot water slightly acidulated with nitric acid, filtered, and cooled the liquid for crystallization. P. C. Ray noted that mercuric nitrate is formed by the action of dil. nitric acid on mercurous nitrite; and J. Lefort, and W. Reuss, by the action of dil. nitric acid on the basic salts of mercury. C. Barfoed noted that a soln. of mercuric nitrate dissolves finely divided mercury, and P. C. Ray showed that when a soln. of mercuric nitrate is violently shaken for a short time with mercury, it is wholly converted into mercurous nitrate, and he recommended this method of preparing a soln. of mercurous nitrate free from nitrous acid. A. Ogg also recommended preparing a neutral soln. of mercurous nitrate by shaking a soln. of mercuric nitrate with mercury, and filtering the soln. from the solid basic nitrate. Analyses of the crystals by C. G. Mitscherlich, C. F. Gerhardt, J. C. G. de Marignac, A. J. Cox, etc., show that monohydrated mercurous nitrate, $\text{HgNO}_3 \cdot \text{H}_2\text{O}$, is in question. J. Lefort's analyses corresponded with the hydrate $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\frac{3}{4}\text{H}_2\text{O}$, but J. C. G. de Marignac showed that the crystals were probably not dry, for they are liable to contain inclusions of the mother liquor; the crystals should be powdered and dried by press. between folds of filter paper. W. Reuss claimed to have produced a whole range of other hydrates with $1\frac{1}{2}$, $1\frac{2}{3}$, $1\frac{1}{3}$, 2 , $2\frac{1}{2}$, $2\frac{1}{4}$, $2\frac{3}{4}$, 3 , and $3\frac{1}{2}\text{H}_2\text{O}$, but this has not been confirmed.

The prismatic **crystals** of the monohydrate were found by J. C. G. de Marignac to belong to the monoclinic system, and to have axial ratios $a : b : c = 1.1503 : 1.08334$, and $\beta = 103^\circ 47\frac{1}{2}'$. The salt does not crystallize isomorphously with the other univalent nitrates. Mercurous nitrate is very hygroscopic. L. Playfair and J. P. Joule³ found the **specific gravity** of the monohydrate to be 4.785 at 3.9° . C. F. Gerhardt found that the crystals of the monohydrate melt readily when heated; J. Lefort gave 70° for the **melting point**. According to J. Lefort, the monohydrate slowly loses all its water when exposed to the air, and rapidly in vacuo over sulphuric acid. The crystals of the hydrate effloresce slightly in air. The salt decomposes into nitrogen peroxide and mercuric oxide when heated to a higher temp. F. Canzoneri found from the lowering of the **freezing point of solutions** in dil.

nitric acid a value corresponding with the mol. wt. $\text{Hg}_2(\text{NO}_3)_2$, and not HgNO_3 ; but A. Ogg showed that too much confidence should not be placed on this result because of the ionization of the solute. With the anhydrous salt, P. W. Bridgman could detect no signs of a transition into another form at temp. between 20° and 90° , and at higher temp. the salt decomposes. The monohydrate probably has a transition at 20° and 8000 kgrms. per sq. cm. press. R. Varet gave for the **heat of formation**, $2\text{Hg}_{\text{liq.}} + \text{N}_2 + 3\text{O}_2 + 2\text{H}_2\text{O}_{\text{liq.}} = 2\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}_{\text{solid}} + 69.4$ Cals.; and J. Thomsen gave $(2\text{Hg}, \text{O}, 2\text{HNO}_{3\text{aq.}}) = 47.99$ Cals.; and $(\text{Hg}_2\text{O}, 2\text{HNO}_{3\text{aq.}}) = 5.79$ Cals. R. Varet gave for the **heat of solution** of $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ in dil. nitric acid, -12.4 Cals. P. T. Muller and E. Carrière found the mean **specific refraction** of soln. of mercurous nitrate in $0.6N$ - to $1.05N$ - HNO_3 in yellow light, to be 0.0843 , i.e. about 7.8 per cent. greater than that of mercuric nitrate; the **specific dispersion** is about 10.5 per cent. greater, being 0.0063 . C. Schaefer and M. Schubert investigated the **infra-red spectrum** of mercury nitrate. A. Ogg found the mol. conductivity, λ , of soln. of mercurous nitrate in $10N$ - HNO_3 increases 34 per cent. when v , the number of litres of soln. per mol. of salt, changes from 5 to 250 . At 18° :

v	5	9	16	32	70	130	225
$\lambda \times 10^7$	51.85	53.72	54.87	55.50	62.25	64.80	69.58

W. Reinders found that mercurous nitrate is not so strongly ionized as silver nitrate in aq. soln. A. Ogg also found that the **decomposition voltages** of soln. of mercurous nitrate are nearly the same as those of soln. of silver nitrate. E. Bouty has measured the **electromotive force** of soln. of mercurous nitrate. R. Behrend measured the e.m.f. of soln. in various organic solvents; and E. Baur, the e.m.f. between a soln. of mercurous nitrate and various organic liquids.

J. von Tugolesoff⁴ argued that the **action of light** always tends to an oxidizing reaction, and cited, *inter alia*, the following:

Ordinary writing paper was soaked in a sat. soln. of mercurous nitrate, dried, and exposed to light. My idea was that, if the action of light were an oxidizing one, an insoluble basic mercuric salt would form where the paper was illuminated and would remain on the paper after the unchanged mercurous nitrate has been washed out. The action of light produced no visible change in the paper; but when the paper had been washed in boiling water, the exposed places assumed a yellowish colour which then changed to a dark grey, making the image fairly distinct. The theory was confirmed. Under the action of light there was formed a colourless, insoluble mercuric salt which was changed by a large excess of water into a yellow salt, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgO} \cdot \text{H}_2\text{O}$. This latter reacted with the excess of mercurous nitrate in the soln., forming mercuric nitrate and mercurous oxide. The mercurous oxide was decomposed by boiling water into oxygen and metallic mercury.

S. Hada found that mercurous nitrate is stable in **air** if not exposed to a bright light. A. Colson found that at 100° , in presence of **hydrogen**, the dried crystals become yellow and give off nitric oxide; and at 100° , they absorb **oxygen**, and form mercuric nitrate; and J. L. Proust said that a soln. of mercurous nitrate exposed to the air, absorbs oxygen, forming mercuric nitrate. A. Mailfert said that **ozone** transforms mercurous nitrate into mercuric nitrate and a basic mercuric nitrate, and Y. Yamauchi that aq. soln. of mercurous nitrate are oxidized by **ozone** to mercuric oxide and nitrate. According to S. Hada, an aq. soln. in darkness and in a closed vessel is quite stable when it is free from nitrous acid, and this even in an atm. of oxygen; there is no evidence that any mercurous salt, moist or in soln., is oxidizable in air at ordinary or moderate temp. The experiments of L. Mailhe on the oxidizability of wet mercurous chloride in air really show that it is the mercurous oxide which is oxidized, for the mercurous salt is decomposed under these conditions into a basic salt. Mercurous salts in the presence of water, or better, in soln., are oxidized in air or oxygen at about 150° . In strong light, mercurous nitrate, moist or in soln., is dissociated at common temp., forming the mercuric salt and mercury—the change is produced by the reduction of its own nitric acid to nitrous acid. Exposure in an open vessel, or to an atm. of mercury vapour or even to oxygen, retards the progress of the change, by keeping down the quantity of nitrous acid which otherwise increases with time. An atm. of carbon dioxide does not impede the change.

Mercurous nitrate is readily changed to mercuric nitrate and nitrite when kept in soln. at 150° under press. J. L. Proust knew that on boiling a soln. of mercurous nitrate, mercury is volatilized with the steam; H. Rose also stated that when mercurous nitrate is continuously boiled with water, it is converted into mercuric nitrate and mercury, but he wrongly thought that the insoluble salt formed when mercurous nitrate is treated with water, contained both mercury and mercuric nitrate. The dissociation of mercurous nitrate noted by J. L. Proust was shown by S. Hada to proceed at lower temp., even to a measurable extent at 40° , provided that the mercury vapour is carried away by a current of air.

According to J. L. Proust, and P. Grouvelle, mercurous nitrate dissolves completely in a small proportion of warm water, but with a larger proportion of water, the salt is hydrolyzed, forming an acid soln. and an insoluble basic salt, which contains less nitrate and more oxide the greater the proportion of water, until finally A. J. Cox found mercuric oxide alone remained. Mercurous nitrate is completely soluble in water acidified with nitric acid; and A. J. Cox found that at least 2.95 N- HNO_3 is necessary at 25° to maintain the mercurous nitrate in soln. The soln. of mercury in cold dil. nitric acid or of mercurous nitrate in dil. nitric acid is the *solutio mercurii frigide parata*—soln. of mercury prepared in the cold. A. Libavius, and J. L. Proust mentioned that if the skin be wetted with this soln. and exposed to light, a purple stain appears which finally becomes black.

When a soln. of mercurous nitrate is treated with **chlorine**, H. Hager found that mercurous chloride, and mercuric nitrate are formed; and R. Varet, that the nitric acid of mercurous nitrate is displaced by **hydrogen chloride**, C. G. Mitscherlich found that when mercurous nitrate is triturated with **sodium chloride**, and the mixture extracted with water, the filtrate contains neither free acid nor mercury; insoluble mercurous chloride and sodium nitrate are formed. J. Myers found mercurous nitrate is reduced to mercury by **potassium hydrosulphide**. L. V. Brugnatelli found that when projected on red-hot **carbon**, mercurous nitrate detonates feebly but with a bright flame. C. W. Scheele observed that when mercurous nitrate is treated with **hydrocyanic acid**, metallic mercury appears; F. John said that mercuric cyanide is simultaneously formed, and M. H. Deschamps that soluble mercuric cyanide, ammonium nitrate, and carbonate are formed. R. Varet found that the nitric acid is displaced from mercurous nitrate by hydrogen cyanide. G. C. Wittstein obtained a white gelatinous precipitate with **potassium ferrocyanide**, and a brown precipitate with **potassium ferricyanide**; H. Arctowsky noted that mercurous nitrate dissolves appreciably in boiling **carbon disulphide**. A. Naumann said that mercurous nitrate is slightly soluble in **benzonitrile**; and H. D. Gibbs that liquid **methylamine** colours the salt black and dissolves it. L. Pesci found that when mercurous nitrate is treated with **ammonia** gas, mercury is formed. E. C. Franklin and C. A. Kraus found that the salt is insoluble in liquid ammonia; and H. Hager, that a glass rod moistened with a soln. of mercurous nitrate held in ammonia vapour, forms a white film which later becomes black. A. F. de Fourcroy noted that aq. ammonia gives a grey precipitate with mercurous nitrate. W. Reuss obtained white crystals of what he regarded as octohydrated **mercurous hydro-pentanitate**, $4\text{HgNO}_3 \cdot \text{HNO}_3 \cdot 8\text{H}_2\text{O}$, by evaporating the mother liquid remaining after the separation of the basic 16 : 9 : 19 salt; and yellow crystals of the acid salt $5\text{HgNO}_3 \cdot 3\text{HNO}_3 \cdot 26\text{H}_2\text{O}$ from the mother liquid remaining after the separation of the basic 8 : 5 : 11 salt. L. V. Brugnatelli found that a mixture of **phosphorus** and mercurous nitrate detonates violently when struck with a hot hammer. H. Rose obtained a black precipitate by passing **phosphine** into a soln. of mercurous nitrate. G. Denigès used mercurous nitrate as a micro-chemical test for **arsenic**; and H. Rosenhaupt used it for producing bronze effects on metals. According to A. Ogg, finely-divided **silver** precipitates mercury from a soln. of mercurous nitrate, and this amalgamates with the silver.

S. Hahnemann⁵ described a product formed by the action of a cold very dil. soln. of mercurous nitrate, as free as possible from an excess of nitric acid and of mercuric nitrate,

on less than an eq. quantity of a dil. aq. or alcoholic soln. of ammonia added very gradually with constant stirring. The precipitate is quickly washed on a filter by means of cold water, pressed between filter paper, and dried in darkness at ordinary temp. Special directions have been given for preparing this compound in many pharmacopœias, and likewise by C. G. Mitscherlich, C. F. Bucholz, F. W. Beissenhirtz, R. Brandes, G. Stein and J. A. W. Büchner, J. S. F. Pagenstecher, G. H. Stolze, A. M. Pleischl, A. Duflos, A. Monheim, etc. The black or greyish-black powder has been called *mercurius solubilis Hahnemanni*, or *Hahnemann's soluble mercury*. According to A. Duflos, when Hahnemann's mercury is exposed to light, it is gradually decomposed into mercury and a basic mercuric nitrate; and when heated in a glass tube it sublimes without residue—the sublimate is mercury; but J. A. W. Büchner said the sublimate is a basic mercuric nitrate. With a soln. of potassium hydroxide, C. G. Mitscherlich obtained a little ammonia, E. Soubeiran obtained none. C. G. Mitscherlich said that baryta water removes part of the acid radicle, while a soln. of barium sulphide takes away all the acid, and drives off ammonia. E. Soubeiran found that with sulphuric acid, nitrous fumes are evolved. C. G. Mitscherlich found boiling hydrochloric acid dissolves Hahnemann's mercury completely, forming a soln. of mercuric and ammonium chlorides; cold hydrochloric acid forms mercurous chloride and dissolves out some mercuric oxide possibly present as an impurity—sometimes a detonating compound is formed with cold hydrochloric acid. According to C. F. Bucholz, cold dil. nitric acid dissolves mercurous oxide or, according to E. Soubeiran, basic mercurous nitrate, and leaves a less soluble white salt which C. F. Bucholz regarded as basic mercurous ammonium nitrate, and E. Soubeiran, as basic mercuric ammonium nitrate. C. F. Bucholz found boiling acetic acid dissolves all Hahnemann's mercury with the exception of a few globules of elemental mercury. C. G. Mitscherlich found it to be resolved by aq. ammonia into mercury and a soluble basic mercuric ammonium nitrate; and G. C. Wittstein found it behaved similarly with soln. of ammonium chloride, sulphate, or nitrate—particularly if heated. According to J. Lefort, Hahnemann's soluble mercury does not yield any globules of mercury when pressed, nor does it amalgamate gold foil. L. Pesci regarded Hahnemann's soluble mercury as a mixture of mercury with $3(\text{NH}_2)_2\text{NO}_3 \cdot \text{NH}_4\text{NO}_3 \cdot 2\text{H}_2\text{O}$, and he represented the reaction: $12\text{HgNO}_3 + 12\text{NH}_3 + 2\text{H}_2\text{O} = 3\text{NHg}_2\text{NO}_3 \cdot \text{NH}_4\text{NO}_3 \cdot 2\text{H}_2\text{O} + 6\text{Hg} + 8\text{NH}_4\text{NO}_3$. Analyses have been made by J. Lefort, C. G. Mitscherlich and A. Duflos, and these correspond with $3\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$; A. Lösch gave $(\text{NH}_2)_2\text{Hg}_2 \cdot \text{Hg}_2(\text{NO}_3)_2$; R. J. Kane gave $2\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5 \cdot 2\text{NH}_3$, and it may possibly be a mercurous amino-nitrate, but E. Soubeiran regarded it as a variable mixture of basic mercurous nitrate, and a salt to which he gave the name *protonitrate ammoniaco-mercuriel*, and which has also been called *Soubeiran's mercurous salt*. The latter was obtained by mixing a soln. of mercurous nitrate with a large proportion of nitric acid, or ammonium nitrate, and precipitating by adding ammonia; or by adding ammonia to a soln. of mercurous nitrate until the precipitate begins to whiten; the filtrate is then precipitated by ammonia. J. S. F. Pagenstecher, C. G. Mitscherlich, R. J. Kane, and E. Soubeiran were unable to agree as to whether this product is a mercurous or mercuric salt. It is now considered to be the nitrate of Millon's base (*q.v.*) mixed with a little mercury. Another old medicinal preparation, called *mercurius cinereus Blackii* or *mercurius cinereus Edinburgensis*, was obtained by precipitating mercurous nitrate with ammonium carbonate. The product is almost identical with Hahnemann's soluble mercury, but gives off a small quantity of carbon dioxide when treated with acids.

J. S. F. Pagenstecher⁶ prepared columnar crystals of **ammonium mercurous nitrate**, $2\text{NH}_4\text{NO}_3 \cdot \text{HgNO}_3$, or $(\text{NH}_4)_2\text{Hg}(\text{NO}_3)_2$, by evaporating a mixed soln. of ammonium and mercurous nitrates. C. F. Rammelsberg found the rhombic bipyramids have axial ratios $a : b : c = 0.6924 : 1 : 0.3649$. The aq. soln. gives a grey precipitate with an aq. soln. of ammonia, or potassium carbonate; the precipitate is a mixture of mercury and $\text{NH}_2\text{HgNO}_3 \cdot \text{NH}_2(\text{HgOHg})\text{NO}_3$. The same salt was probably obtained by J. A. W. Büchner in the preparation of Hahnemann's mercury, but he regarded it as a basic mercurous nitrate.

The basic mercurous nitrates.—The hydrolysis of normal mercurous nitrate by water results in the formation of a basic salt and an acidic soln. The various reports of this action are confused. The basicity of the product is dependent on the quantity of water, on the temp., and on the time the reacting components are in contact. W. Reuss⁷ stated that the water of crystallization is directly proportional to the number of salt-forming atoms of mercury in the product; that most of the basic salts crystallize in the rhombic system, a few in the monoclinic system; that the basic salts resist chemical and physical influences better than the normal salt; that unlike the normal salt, the basic salts do not smell of nitric acid; and that the water of crystallization usually remains when the salt is exposed to the air or kept in vacuo. A. J. Cox added that the mercuric salts are more susceptible to hydrolysis than the mercurous salts.

According to A. J. Cox, the mercurous nitrates which can be formed in aq. soln. are the monohydrate, $\text{HgNO}_3 \cdot \text{H}_2\text{O}$, in colourless crystals; white pulverulent $5\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$; a dirty-white product between $3\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5$ and $2\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5$, but whose existence is uncertain since it has not been isolated, though it appears to be formed by the hydrolysis of mercurous nitrate at 12° ; a product darker than the preceding, $2\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5$; yellowish-green $3\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, whose existence is certain but whose composition is not definitely known. The results are shown graphically in Fig. 39, where the ordinates represent the number of mols of $(\text{H}, \text{Hg})\text{NO}_3$ per litre of soln., and the abscissæ, the increased basicity x of the solid phase $10\text{HgNO}_3 - x\text{N}_2\text{O}_5$. The greenish-yellow basic salt, $3\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, or $2\text{Hg}_2\text{O} \cdot 2\text{HgNO}_3 \cdot 2\text{H}_2\text{O}$, or $2\text{HgOH} \cdot \text{HgNO}_3$, **monohydrated mercurous dioxynitrate**, was prepared by A. J. Cox

FIG. 39.—Basic Mercurous Nitrates.

by the hydrolysis of mercurous nitrate at 25° ; an acid conc. of at least $0.0017N\text{-HNO}_3$ is necessary. The salt decomposes at 90° . A. J. Cox found an acid conc. of at least $0.110N\text{-HNO}_3$ at 25° to be necessary for the formation of **mercurous oxydinitrate**, $\text{Hg}_2\text{O} \cdot 2\text{HgNO}_3$; but the compound was not isolated—*vide* Fig. 39.

C. F. Gerhardt's *sous-nitrate sesquimercuroux* had the composition $3\text{Hg}_2\text{O} \cdot 2\text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, or $\text{Hg}_2\text{O} \cdot 4\text{HgNO}_3 \cdot \text{H}_2\text{O}$, or $\text{HgOH} \cdot 2\text{HgNO}_3$, **mercurous hydroxydinitrate**. C. G. Mitscherlich prepared colourless prismatic crystals of this salt by leaving mercurous nitrate in the acid mother liquid in which it was prepared until the crystals have dissolved and been replaced by the crystals of the new salt; and by heating mercurous oxide with dil. nitric acid. C. G. Mitscherlich found the crystals obtained by these two processes are different, and hence stated that the salt is dimorphous; but C. F. Gerhardt showed that this is a mistake because the second process furnishes crystals of $5\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$. The salt was also made by J. C. G. de Marignac, C. F. Gerhardt, J. Lefort, and L. Mailhe. While C. G. Mitscherlich's analysis corresponds with the ratio $\text{Hg}_2\text{O} : \text{N}_2\text{O}_5 : \text{H}_2\text{O} = 3 : 2 : 3$, that of C. F. Gerhardt's corresponds with $3 : 2 : 1$; that of J. Lefort, with $3 : 2 : 2\frac{1}{2}$; and that of J. C. G. de Marignac's with $4 : 3 : 1$ —*vide infra*. R. J. Kane believed the salt to be a mixture of normal mercurous nitrate with the $2 : 1 : 1$ salt.

R. J. Kane prepared **monohydrated mercurous oxydinitrate**, $\text{Hg}_2\text{O} \cdot 2\text{HgNO}_3 \cdot \text{H}_2\text{O}$, *i.e.* **mercurous hydroxynitrate**, $\text{HOHg} \cdot \text{HgNO}_3$, also called *nitrous turpeth*. C. F. Gerhardt called it *sous-nitrate bimercuroux*; and J. Lefort's analysis corresponded with $2\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, but his preparation was probably not well enough dried. This basic salt is obtained by washing basic or normal mercurous nitrate with cold water until it has acquired a yellow colour. The hydrolysis is more quickly produced by boiling water, but the action must be stopped as soon as a grey coloration appears owing to the separation of mercury; the reaction is also hastened by a little potassium hydroxide, but the product is then more impure. The grey powder obtained by M. Donovan by treating this salt with a soln. of potassium hydroxide is not a basic salt, but a mixture of the yellow salt with mercurous oxide. R. J. Kane also prepared the yellow salt in needle-like crystals when a soln. of mercurous nitrate is allowed to stand a long time over mercury. According to J. C. G. de Marignac, one part of powdered mercurous nitrate is agitated with ten parts of boiling water; and the yellow powder is washed by decantation with cold water. It should be dried in darkness. P. C. Ray obtained this salt from mercurous nitrite which he found to change into mercuric nitrite, which is

readily hydrolyzed, forming mercuric hydroxynitrate which reacts with mercurous nitrate, forming mercurous hydroxynitrite: $2\text{Hg}_2(\text{NO}_3)_2 + 3\text{Hg} + \text{Hg}(\text{NO}_2)_2 + 2\text{H}_2\text{O} = 2\text{NO} + 4(\text{HOHg}.\text{HgNO}_3)$. When this salt is heated, it gives off red vapours containing some nitric acid, and mercuric oxide remains. R. J. Kane, and J. C. G. de Marignac noted that it is gradually blackened when boiled with water; the water afterwards contains some mercuric nitrate.

J. C. G. de Marignac prepared $5\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, or $4(\text{HOHg}.\text{HgNO}_3) \cdot 2\text{HgNO}_3$, or $2\text{HgOH} \cdot 3\text{HgNO}_3$, **mercurous dihydroxytrinitrate**, by boiling for many hours with mercury the soln. or the mother liquid remaining after the preparation of mercurous nitrate or of the basic nitrate, $4\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, replacing the water as it evaporates; and also by leaving the two last-named salts in contact with their mother liquids and mercury at ordinary temp. C. F. Gerhardt made it by suspending mercurous nitrate in a little water which was heated to the b.p. and allowed to cool; L. Pesci, by allowing a soln. of mercurous nitrate with the smallest possible quantity of nitric acid to stand in an atm. containing some ammonia gas; J. Lefort, by evaporating to dryness the soln. obtained by the action of conc. nitric acid on mercury, and extracting the product with boiling water; by mixing a soln. of mercurous nitrate with potassium hydrocarbonate until a precipitate is produced, and allowing the clear liquid to crystallize by evaporation; and also by heating dil. nitric acid to 40° – 80° in contact with mercury for a long time; A. J. Cox, by the hydrolysis of a soln. of mercurous nitrate at 25° , Fig. 39, and he showed that an acid conc. of at least $0.293N$ - HNO_3 is necessary for its existence in soln.; and P. C. Ray, by the slow action of dil. nitric acid on mercurous nitrite, and by the hydrolysis of a soln. of mercurous nitrite. There has been a controversy as to the exact composition of this salt; J. C. G. de Marignac gave the ratio $\text{Hg}_2\text{O} : \text{N}_2\text{O}_5 : \text{H}_2\text{O}$ as $5 : 3 : 2$. C. F. Gerhardt gave $2 : 1 : 1$, and J. Lefort gave $2 : 1 : 2$. The analyses of P. C. Ray, and A. J. Cox agree with those of J. C. G. de Marignac. The clear, colourless, prismatic crystals are triclinic pinacoids with axial ratios and angles, according to J. C. G. de Marignac, and C. F. Rammelsberg, of $a : b : c = 1.3061 : 1 : 1.1904$, and $\alpha = 94^\circ 2'$, $\beta = 109^\circ 40'$, and $\gamma = 101^\circ 16'$. According to P. C. Ray, the crystals retain their lustre when exposed to air, or when confined over conc. sulphuric acid in vacuo. If heated for about 3 hrs. the crystals lose their water and form $5\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5$; and they decompose when rapidly heated to 90° in an air-bath. W. Reuss also reported the hydrates $5 : 3 : 2$; $5 : 3 : 4$; and $5 : 3 : 6$.

J. C. G. de Marignac obtained the $4 : 3 : 1$ salt, or $3\text{HgNO}_3.\text{HgOH}$, **mercurous hydroxytrinitrate**, by heating crystals of mercurous nitrate with the mother liquid from which they separated, and an excess of mercury; and cooling the soln. J. Lefort boiled mercury with nitric acid of sp. gr. 1.42 diluted with 5 vols. of water for 5 or 6 hrs. and replaced the water as it evaporates. If the mixture is not boiled long enough, the $5 : 3 : 2$ salt is produced. P. C. Ray prepared the salt by digesting 50 grms. of mercury and 75 grms. of nitric acid of sp. gr. 1.2, first cold, and then warm; the crop of crystals of mercurousmercuric nitrate which separates from the hot soln. is removed, and the $4 : 3 : 1$ salt crystallizes out on cooling. P. C. Ray obtained the same salt by the hydrolysis of mercurous nitrate. The crystals form colourless needles or prisms which, according to J. C. G. de Marignac, are rhombic bipyramids with axial ratios $a : b : c = 1.1132 : 1 : 0.9255$. The crystals do not change in air or in vacuo; but at 100° they become yellow, and lose water. J. Lefort gave the formula $6 : 4 : 3$, and there is some confusion in literature between this and the $3 : 2 : 1$ salt. W. Reuss also described the hydrate $4 : 3 : 5$, and reported products $8 : 5 : 5$; and $8 : 5 : 11$.

§ 35. Mercuric Nitrate

A soln. of mercuric nitrate, $\text{Hg}(\text{NO}_3)_2$, the so-called *solutio mercurii calide parata*—soln. of mercury prepared by heat—of the older chemists, is readily obtained by dissolving mercuric oxide in nitric acid; and by boiling mercury or mercurous nitrate with an excess of nitric acid until a drop diluted with water

no longer becomes turbid when treated with a soln. of sodium chloride. For a long time it was supposed that the soln. of mercuric nitrate was uncrystallizable; J. L. Proust obtained a syrupy liquid of sp. gr. 3.47, but both J. L. Proust, J. A. W. Büchner, and C. G. Mitscherlich¹ showed that when the soln. is conc. by evaporation and cooled, it furnishes crystals of a basic salt. A similar product is obtained by crystallization from the filtrate from a mixture of soln. of mercuric chloride and silver nitrate. According to E. M. Walton, when a dry mixture of silver nitrate and mercuric chloride is triturated, the product appears moist owing to the formation of liquid mercuric nitrate.

N. A. E. Millon and R. Varet obtained large crystals of **hemihydrated mercuric nitrate**, $\text{Hg}(\text{NO}_3)_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, by evaporating the soln. over sulphuric acid or quicklime; and the former also found that a mush of crystals is precipitated when fuming nitric acid is added to a soln. conc. as much as possible by evaporation. A. J. Cox prepared long transparent crystals of **monohydrated mercuric nitrate**, $\text{Hg}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$, by saturating 50 per cent. nitric acid with commercial mercuric nitrate, evaporating the soln. under diminished press., and drying the crystals by press. between filter paper. He found that if the conc. of free acid in the soln. is not less than 18.72N- HNO_3 at 25°, no basic salt crystallizes out. H. V. Regnault obtained clear colourless plates of what he regarded as **octohydrated mercuric nitrate**, $\text{Hg}(\text{NO}_3)_2 \cdot 8\text{H}_2\text{O}$, by cooling to -15° a nearly neutral soln. conc. as much as possible by evaporation; but N. A. E. Millon showed that such a soln. has less water than is represented by the octohydrate. The great hygroscopicity of the crystals has possibly led to erroneous conclusions being drawn from the analytical work; and it has also prevented accurate measurements being made of the physical properties.

The **crystals** of the hemihydrate are simply described by R. Varet as being transparent; those of the monohydrate, by A. J. Cox, as being long and transparent; and those of the octohydrate, by H. S. Ditten, as clear, colourless rhombic plates. J. W. Retgers said that the **specific gravity** of mercuric nitrate (hemihydrated) is 4.3; and that the **melting point** is 79°. N. A. E. Millon said that the crystals of the hemihydrate are slowly decomposed giving off nitric acid when allowed to stand over conc. sulphuric acid. H. S. Ditten said that the octohydrate melts in a warm room; and A. Ditte added that after melting, it gives off water and nitric acid, and leaves behind a white powder which is decomposed by water into free acid and a yellow basic nitrate. P. W. Bridgman detected no signs of a transition into another form at 20° and increasing press. up to 12,000 kgrms. per sq. cm.; at 180° and 1000 kgrms. per sq. cm. press., the salt decomposed with explosive violence. J. Schröder and H. Steiner found the **raising of the boiling point** of soln. in methyl acetate corresponded with the **molecular weight**, $\text{Hg}(\text{NO}_3)_2$; F. M. Raoult also inferred the formula $\text{Hg}(\text{NO}_3)_2$ from the **freezing point of solutions** of mercuric oxide in nitric acid. R. Varet estimated the **heat of formation** to be $\text{Hg}_{\text{liq.}} + \text{H}_{2\text{gas}} + 3\text{O}_{2\text{gas}} + \frac{1}{2}\text{H}_2\text{O}_{\text{liq.}} = \text{Hg}(\text{NO}_3)_2 \cdot \frac{1}{2}\text{H}_2\text{O}_{\text{solid}} + 57.4$ to 58.36 Cals., and with the precipitated oxide and dil. nitric acid: $\text{HgO} + \text{HNO}_{3\text{aq.}} = \text{Hg}(\text{NO}_3)_2 \cdot \frac{1}{2}\text{H}_2\text{O}_{\text{liq.}} + 7.3$ Cals. J. Thomsen gave $(\text{Hg}, \text{O}, 2\text{HNO}_{3\text{aq.}}) = 37.07$ Cals., and $(\text{HgO}, 2\text{HNO}_{3\text{aq.}}) = 6.4$ Cals. R. Varet gave for the **heat of solution** in dil. nitric acid, -0.7 Cal. The hydrolytic decomposition accounts for the low heat of soln. in spite of its being an endothermal reaction. S. M. Tanatar and L. Pissarjewsky found the heat of soln. in an aq. soln. of calcium chloride to be 11.545 Cals., and very small in alcohol; the heat of the reaction with an alcoholic soln. of sodium hydroxide is 19.864 Cals. R. Varet estimated that the reduction of mercuric to mercurous nitrate develops 9.9 Cals.

According to P. T. Muller and E. Carrière, the mean **specific refraction** of the soln. in 0.6N- to 1.05N- HNO_3 in yellow light is 0.0782, and the **specific dispersion** 0.0057. D. Gernez studied the **triboluminescence** of the crystals. F. Teltscher measured the eq. **electrical conductivity**, λ , of aq. soln. of mercuric nitrate, and found for n mols of the salt per litre:

$n\text{-Hg}(\text{NO}_3)_2$. . .	0.0730	0.1460	0.1620	0.3420	0.1620
λ	. . .	114.0	124.5	110.0	133.5	144.5
$n\text{-HNO}_3$. . .	0.029	0.059	0.011	0.0225	0.122
$n\text{-Hg}^{++}\text{-ions}$. . .	0.046	0.056	0.092	0.124	0.038

This scheme also shows the estimated hydrolysis and **degree of ionization** of soln. of mercuric nitrate. H. N. Morse also calculated the ionic conc. of soln. of mercuric nitrate. E. Abel agitated soln. of mercuric nitrate in 0.3*N*-HNO₃ until equilibrium was attained, and the conc. of the mercurous and mercuric salts in the soln. were determined on the assumption that these conc. were nearly proportional to the conc. of the corresponding ions. The ratio $[\text{HgNO}_3]/[\text{Hg}(\text{NO}_3)_2]$ was found to be constant and nearly equal to 239.5 at 25°, showing that the two ions have the same valency, and that the reaction takes place in accord with the equation $\text{Hg}^{++} + \text{Hg} = \text{Hg} \cdot \text{Hg} \cdot$, where the mercurous ion consists of two atoms. R. Varet also assumed that soln. of mercuric nitrate in dil. nitric acid contained neither an acid nor a basic salt. H. N. Morse studied the **transport numbers**.

Some chemical properties of mercuric nitrate.—V. H. Veley² found that mercuric nitrate is reduced to mercurous nitrate by **hydrogen**. The hydrolytic action of **water** has been indicated above, and it is further discussed in connection with basic salts. W. Sievers found that with **chlorine**, hypochlorous and nitric acids, and mercuric chloride are formed; and that **bromine** acts similarly. According to J. Spiller, bromine has no action on mercurous salts. H. Saha and K. N. Choudhuri obtained a black substance by the action of aq. **ammonia**—*vide* the mercury ammonium nitrates. E. C. Franklin and C. A. Kraus found mercuric nitrate to be readily soluble in liquid ammonia; V. H. Veley found **nitric oxide** reduces a soln. of mercuric nitrate like hydrogen, and E. Divers and T. Haga, that nitric oxide, or an **alkali nitrite**, furnishes hydroxylamine. A. Ditte found that monohydrated **nitric acid** dissolves no octohydrated mercuric nitrate in the cold, and but traces when heated; H. Rose obtained a yellow precipitate by passing **phosphine** into a soln. of mercuric nitrate; the yellow precipitate then became white. When washed in water and dried over sulphuric acid, the yellow colour was restored. The composition is $\text{P}_2\text{Hg}_3 \cdot 6\text{HgO} \cdot 3\text{N}_2\text{O}_5$. The compound explodes when heated or by percussion. B. E. Howard showed that **hypophosphorous acid** reduces the salt violently to the metal; and H. Erdmann and P. Köthner, that **acetylene** gives with aq. soln. of mercuric nitrate a white crystalline precipitate which again gives off acetylene when boiled with dil. acids, and when heated, or treated with conc. sulphuric acid, an explosion occurs; J. Schröder reported that mercuric nitrate is soluble in **pyridine**; W. Eidmann, in **methylal**; and A. Naumann, in **acetone**. G. C. Wittstein obtained a white precipitate with **potassium ferrocyanide**, and a yellow precipitate with **potassium ferricyanide**. R. Cowper found that a compound, $(\text{C}_2\text{H}_2\text{Hg}_3\text{O}_2)(\text{NO}_3)_2$, is formed when mercuric nitrate is treated with **alcohol**. When a soln. of mercuric nitrate is added to ordinary alcohol, **mercury fulminate**, with the empirical formula $\text{HgC}_2\text{N}_2\text{O}_2$, is obtained; silver nitrate furnishes a corresponding *silver fulminate*, AgCNO . The various modes of formation of these salts—principally its spontaneous formation from isonitromethane, $(\text{CH}_2)\text{O} \cdot \text{NO} \cdot \text{Hg}$, at 0°; and from formylchloride oxime, $\text{H}(\text{Cl})\text{C} \cdot \text{NOH}$, by the action of silver nitrate—and its reaction with dil. hydrochloric acid, whereby hydrogen cyanide is formed, have led to the view that the fulminates are salts of monobasic *fulminic acid*, $\text{HO}-\text{N}=\text{C}$, silver fulminate thus becomes $\text{AgO}-\text{N}=\text{C}$, and mercuric fulminate, $\text{Hg}(\text{ONC})_2$. The decomposition of mercury fulminate has been studied by A. Langhans. Many complex compounds of mercuric nitrate with other organic compounds—dimethylethylene, trimethyl carbinol, salicylic acid, urea, thiourea, etc.—have been prepared by G. Denigès, H. Lajoux and A. Grandval, C. J. Lintner, H. Byasson, J. E. Reynolds, etc. According to W. Biltz and F. Zimmermann, a soln. of mercuric nitrate colours the freshly precipitated **hydrogels** of beryllium, magnesium, cadmium, lead, and erbium hydroxides, yellowish-red; those of zinc, aluminium, manganese, lanthanum, praseodymium, and neodymium, yellow;

while those of indium, zirconium, antimony, and bismuth gave no coloration. H. N. Morse has studied the solubility of the silver halides in aq. soln. of mercuric nitrate; H. Debray and H. W. F. Wackenroder found that **silver chloride, bromide, and iodide, and mercurous chloride** are readily dissolved; and J. Schlesinger, and H. W. F. Wackenroder found that **mercurous chloride, bromide, and iodide, mercuric iodide, and silver cyanide and thiocyanate** are readily dissolved. J. W. Retgers found molten **mercuric acetate** dissolves but little mercuric nitrate.

The basic compounds of mercuric nitrate.—G. F. Hildebrandt³ reported that some of the products formerly described, though basic, appear to react acid to litmus. K. Thümmel observed that the hydrolysis of mercuric nitrate progresses further the greater the proportion of water employed. G. Watson represented

FIG. 40.—Basic Mercuric Nitrates.

them not as compounds of normal salt and base, but as derivatives of orthonitric acid. R. J. Kane, and P. Grouvelle reported several yellow basic salts which were probably mixtures. A. J. Cox investigated the various mercuric nitrates which can be formed in aq. soln. at 25°. The results are shown graphically in Fig. 40, when the ordinates represent the number of mols of $(H, Hg_{\frac{1}{2}})NO_3$ per litre of soln., and the abscissæ the increased basicity x of the solid phase $3Hg(NO_3)_2 - xN_2O_5$. A. J. Cox found only **mercuric dioxynitrate**, $2HgO.Hg(NO_3)_2$, to be formed in aq. soln. The limits of existence are with soln. between 18.715N-HNO₃ and 0.159N-HNO₃ at 25°; and 17.930N-HNO₃ and 0.136N-HNO₃ at 15°. It was washed with dil. nitric

acid, pressed between filter paper, and dried in air at 95°. N. A. E. Millon obtained the same product by drying his monohydrate at 120°. The heavy white powder was found by N. A. E. Millon to begin to decompose at 260°, and the decomposition is vigorous at the b.p. of mercury. When continuously washed with cold water for some time, it appears pale pink, and the colour gradually deepens and approaches that of red mercuric oxide; boiling water acts more rapidly forming mercuric oxide, as was also noted by L. V. Brugnatelli and C. G. Mitscherlich. R. J. Kane, and J. Murray said that long boiling does not yield mercuric oxide alone; J. W. Döbereiner also obtained a very small yield of the oxide. N. A. E. Millon found an aq. soln. of alkali sulphate converts it into the basic sulphate; alkali chloride, forms a basic chloride; and alkali chromate, a basic chromate. N. A. E. Millon, and R. Varet claimed to have made the **monohydrated mercuric dioxynitrate**, $2HgO.Hg(NO_3)_2.H_2O$, by washing the basic nitrate, $HgO.Hg(NO_3)_2.H_2O$, or the normal nitrate with cold water. The former also obtained it by heating mercuric nitrate until it forms a pulverulent white mass, washing 7-8 times with cold water, and drying over sulphuric acid. It was claimed that 2.62 per cent. of water is lost at 120°. R. Varet gave for the heat of formation with precipitated mercuric oxide, $3HgO + 2HNO_{3dil} = 3HgO.N_2O_5.H_2O_{solid} + 15.45$ Cals.; and $HgO.N_2O_5.\frac{1}{2}H_2O_{solid} + 2HgO + \frac{1}{2}H_2O = 3HgO.N_2O_5.H_2O_{solid} + 8.092$ Cals.

N. A. E. Millon reported monohydrated **mercuric oxynitrate**, $HgO.Hg(NO_3)_2.H_2O$, to be formed by saturating nitric acid of sp. gr. 1.45 with mercuric oxide; and also by digesting yellow mercuric oxide for 50 days with an excess of an acidified soln. of mercuric nitrate. A. Mailhe also obtained it by the action of cupric hydroxide, $4CuO.H_2O$, or $CuO.H_2O$, or of nickel hydroxide, or carbonate on a cold soln. of mercuric nitrate; and also in clinorhombic prisms or plates by crystallization from cold sat. soln. of mercuric oxide in a soln. of uranyl nitrate, or in hot soln. of

aluminium nitrate, or ferric nitrate. It appears either as a yellow crystalline powder or in monoclinic prisms. It is possible that this salt is really the dihydrate, $\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, or $\text{HO} \cdot \text{Hg} \cdot \text{NO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, obtained by C. G. Mitscherlich by evaporating and cooling an acidified soln. of mercuric nitrate. According to J. C. G. de Marignac, and C. F. Rammelsberg, the crystals are rhombic bipyramids with axial ratios $a : b : c = 0.6976 : 1 : 0.5186$. M. Donovan, and R. J. Kane found that this compound decomposes on exposure to moist air. The latter also obtained a yellow basic nitrate, $3\text{HgO} \cdot \text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, and mercuric oxide when treated with cold water, and finally, according to C. G. Mitscherlich, mercuric oxide alone. The aq. extract, said R. J. Kane, furnishes the original salt when evaporated and cooled. C. G. Mitscherlich found that the salt decomposes when heated into nitric acid and mercuric oxide, and, when triturated with sodium chloride and then with water, soluble mercuric chloride and an insoluble red oxychloride are formed. This basic nitrate dissolves in nitric acid. H. S. Ditten claimed to have obtained colourless needle-like crystals of a trihydrate, $\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, from the liquid obtained by melting octohydrated mercuric nitrate. K. Thümmel prepared a basic nitrate, $\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2$, with an undetermined amount of water, by adding sodium carbonate or hydrocarbonate to a soln. of mercuric nitrate.

B. Finzi found that freshly precipitated silver chloride is soluble in an aq. soln. of mercuric sulphate. The solubility increases (but not in proportion) with the amount of mercuric salt present, but it is increased more by dilution, so that the greatest amount of silver chloride is dissolved by a large excess of mercuric salt at considerable dilution. When to such a soln. hydrochloric acid is added in quantity eq. to the silver present, the metal is not all precipitated. The soln. probably contains **silver mercuric sulphatochloride**. Similar results are obtained when hydrochloric acid is added to a soln. of silver sulphate and mercuric sulphate. The soln. probably contains **silver mercuric sulphate**. The amount of silver chloride remaining dissolved increases with the amount of mercury present, but not proportionately. When the precipitated silver chloride has been filtered, the filtrate gives a further precipitate with hydrochloric acid or chlorides, and with silver nitrate, whilst sulphates, nitrates, and alkali acetates cause no precipitation. **Silver mercuric nitrate** and acetate have been similarly made. Similar phenomena have been observed with the mercuric nitrates and acetates. Yellow mercuric oxide dissolves in warm soln. of silver nitrate, sulphate, or acetate. A boiling soln. of silver sulphate, sat. in the cold, is treated with yellow mercuric oxide until no more dissolves. The filtered soln. deposits small rhombic tablets of pale yellow **silver mercuric oxysulphate**, $\text{Ag}_2\text{SO}_4 \cdot \text{HgO}$; a 2*N*-soln. of silver nitrate, similarly treated, gives tufts of acicular crystals of reddish-yellow **silver mercuric oxynitrate**, $\text{AgNO}_3 \cdot 2\text{HgO}$; and a hot almost sat. soln. of cupric nitrate, similarly treated, gives **cupric mercuric oxynitrate**, $\text{Cu}(\text{NO}_3)_2 \cdot \text{HgO} \cdot 3\text{H}_2\text{O}$, in pale blue acicular crystals.

Complex salts with mercuric nitrate.—There are some mixed basic nitrates which appear to contain both mercurous and mercuric oxides. F. Teltscher⁴ measured the potential of mixed soln. of the two nitrates. P. C. Ray regards many of these mixed basic salts as containing the group $\text{HO} \cdot \text{Hg}_2\text{NO}_3$ analogous with $\text{Hg}_2(\text{NO}_3)_2$. He obtained a basic salt with the empirical composition, $2\text{Hg}_2\text{O} \cdot \text{HgO} \cdot \text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, which can be regarded as an **oxymercurosic hydroxynitrate**, $\text{HgO} \cdot 2(\text{HO} \cdot \text{Hg}_2\text{NO}_3)$. It was at first thought that this compound was a nitrite, but it was later shown to be a nitrate. This salt was prepared in orange-yellow crystalline masses by the evaporation of the mother liquor obtained in the preparation of mercurous nitrite: $4\text{HgNO}_2 + \text{Hg}(\text{NO}_2)_2 + \text{H}_2\text{O} = 4\text{NO} + \text{HgO} \cdot 2\text{Hg}_2\text{O} \cdot \text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$. P. C. Ray also prepared a second oxymercurosic hydroxynitrate, $\text{HgO}(\text{HO} \cdot \text{Hg} \cdot \text{NO}_3)(\text{HO} \cdot \text{Hg}_2 \cdot \text{NO}_3)$ —the former was designated the α -salt, and the latter the β -salt. The latter was obtained from the mother liquor remaining after the preparation of mercurous nitrite; by evaporating soln. of mercury in nitric acid, sp. gr. 1.11 to 1.2 at 35°; at 22°, the basic mercurous nitrate, $4\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5 \cdot \text{H}_2\text{O}$, is formed.

H. Fürth reported a **mercurous oxynitrate**, $\text{HgO} \cdot \text{Hg} \cdot \text{NO}_3$, to be formed when acetamide is treated with mercurous nitrate, or when a soln. of yellow mercuric oxide in an aq. soln. of mercurous nitrate is boiled until its colour becomes yellowish-green. C. F. Gerhardt, and T. Brooks prepared a substance with the same ultimate composition by dissolving 2 parts of mercury completely in 3 parts of boiling nitric acid of sp. gr. 1.2; and C. F. Gerhardt made it by melting mercurous nitrate whereby nitric oxide is given off. According to T. Brooks, the yellow powder decrepitates at 100° , and becomes dark yellow, but the colour becomes paler on cooling. Very little change occurs at 200° , red vapours are given off at 260° , and it becomes dark red, at a higher temp., when mercuric oxide is formed. It becomes brownish-red when triturated with sodium chloride, and water extracts some mercuric chloride from the mass. When boiled with water and exposed to air, the mercurous nitrate is oxidized to mercuric oxide and mercury, but if air be excluded, some mercuric nitrate and a trace of mercurous nitrate dissolve, and the insoluble residue contains both oxides; and when digested with barium carbonate and water, all the nitric acid appears in the aq. soln. H. Fürth found that his product is blackened with ammonia; and it gives off no ammonia when digested with a soln. of sodium sulphide and hydroxide.

H. Rose⁵ and D. Vitali made **mercuric nitratodisulphide**, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgS}$, by passing insufficient hydrogen sulphide into a soln. of mercuric nitrate, to precipitate all the mercury as sulphide. The precipitate was quickly washed with cold water. N. Tarugi added thioacetic acid to a cold soln. of mercuric nitrate; extracted the washed and dried precipitate with carbon disulphide; and dried the product in vacuo. C. Barfoed made it by treating the precipitate obtained by the action of hydrogen sulphide on a mercurous salt, with a soln. of mercuric nitrate, or with cold fuming nitric acid, or hot dil. nitric acid; or, according to J. L. Howe, with boiling acid of sp. gr. 1.42 and a drop of dil. hydrochloric acid (1:3). If 10 drops of hydrochloric acid is added, the whole is dissolved. Only a trace of sulphuric acid, but much mercuric nitrate, is produced. The product is washed until free from acid, and dried first at 40° – 50° , and then at 100° . K. Heumann treated cinnabar containing free mercury with dil. nitric acid; R. Palm digested black mercuric sulphide with a soln. of mercuric nitrate; R. Palm also treated a soln. of black mercuric sulphide in one of mercuric acetate with nitric acid or an alkali nitrate; and N. Tarugi treated mercuric thioacetate with warm conc. nitric acid. The nitratodisulphide is a white powder which when heated in a tube was found by H. Rose to decompose into nitrous fumes, sulphur trioxide, mercury, and mercuric sulphide. When boiled with water, C. Barfoed found it to acquire a grey colour, but very little dissolves; he also stated that it dissolves in hydrochloric acid, with the evolution of nitric oxide, the separation of sulphur, and the formation of sulphuric acid. H. Rose found that it is decomposed by hot aqua regia, forming sulphuric acid, and he stated that when suspended in water, and treated with hydrogen sulphide, it is converted into mercuric sulphide and nitric acid. According to C. Barfoed, when heated with sulphuric acid, of sp. gr. 1.84, it gives off sulphur dioxide, and is transformed into mercuric sulphate; if the sulphuric acid contains a little water, nitric acid and no sulphur dioxide are formed—mercuric sulphate and sulphide are produced. N. Tarugi found that the nitratodisulphide is blackened by ammonia. H. Rose said that it is not decomposed by nitric acid; N. Tarugi, that it is slightly decomposed; and J. L. Howe, that it dissolves if the nitric acid contains a small proportion of hydrochloric acid. According to K. Haack, cold soln. of sodium hydrophosphate or hydroarsenate act slowly on mercuric sulphatodisulphide, and hot soln. form black mercuric sulphide; it is also decomposed by phosphoric and arsenic acids, and by sodium dihydrophosphate and dihydroarsenate. H. Rose said that cold aq. soln. of the alkali carbonates gradually change the colour yellow and finally black; with boiling soln., the compound is blackened at once.

F. Gramp prepared a complex product $\text{HgO} \cdot 6\text{HgS} \cdot 2\text{Hg}(\text{NO}_3)_2 \cdot 12\text{H}_2\text{O}$, by heating to

120° in a sealed tube a mixture of cinnabar, or, better, the black sulphide with nitric acid of sp. gr. 1.2. The white crystalline product loses seven mols of water at 150°. It is insoluble in water, and in cold nitric acid of sp. gr. 1.2, the hot acid attacks the product and leaves a residue of mercuric sulphide. It is decomposed by a soln. of sodium chloride, forming mercuric sulphide and chloride, and sodium nitrate and hydroxide. It is gradually blackened by potassium hydroxide.

C. Kosmann⁶ prepared **ammonium mercuric nitratotetrachloride**, $\text{NH}_4\text{NO}_3 \cdot 2\text{HgCl}_2$, by the action of cold, conc. nitric acid on mercuric amidochloride, and warming the soln. On evaporation silvery-white plates are formed. Water does not dissolve the crystals, but the liquid gradually becomes turbid; a boiling soln. of potassium hydroxide gives only a little ammonia; ether extracts much mercuric chloride. K. A. Hofmann and E. C. Marburg passed nitric oxide into a cold soln. of mercuric diammino-chloride in absolute alcohol. The soln. is conc. by evaporation, and colourless needles of **diammonium mercuric dinitratodichloride**, $2\text{NH}_4\text{NO}_3 \cdot \text{HgCl}_2$, are obtained by adding methyl alcohol. The aq. soln. is strongly acid; it gives ammonia when heated with potassium hydroxide; and chlorine with hot sulphuric acid. V. Borelli did not isolate **mercuric nitratochloride**, $\text{NO}_3 \cdot \text{Hg} \cdot \text{Cl}$, but he deduced its existence from the conductivity of a soln. of mercuric nitrate containing mercuric chloride. H. N. Morse obtained **mercuric nitratobromide**, $\text{NO}_3 \cdot \text{Hg} \cdot \text{Br}$, from a soln. of the component salts. V. Borelli obtained what he regarded as crystals of **mercuric nitratiodide** by cooling a conc. soln. of mercuric chloratiodide in conc. nitric acid. The 1:1 iodide, $\text{Hg}(\text{NO}_3)_2 \cdot \text{HgI}_2$, or $\text{NO}_3 \cdot \text{Hg} \cdot \text{I}$, was prepared by J. Preuss by mixing a boiling soln. of mercuric nitrate of sp. gr. 1.35 with enough nitric acid to prevent it becoming turbid in water, and an excess of iodine, when white tabular crystals separate on cooling; W. Sievers used mercuric iodide in place of iodine. A. Souville, C. H. Hirzel, K. Kraut, treated a soln. of mercurous or mercuric iodide with hot nitric acid; half the iodine volatilizes, some nitrous fumes are evolved, and the crystals were pressed between paper since they are decomposed by washing with water or alcohol—E. Riegel said that the decomposition is less with ether. P. Lemoult obtained crystals of the same salt by the action of nitric acid on mercuric iodophosphide, $\text{Hg}_3\text{I}_3\text{P}$. The crystals melt when heated, and give off nitrous fumes, mercuric iodide volatilizes, and mercuric oxide remains. The crystals are rapidly decomposed by water, forming mercuric iodide, and soluble mercuric nitrate; A. Souville found that alcohol of sp. gr. 0.814 decomposes the salt; and E. Riegel stated that the decomposition is less with ether. According to J. Preuss, an aq. soln. of ammonia or potassium hydroxide separates mercuric oxide, and ammonium or potassium mercuric iodide is formed. J. von Liebig reported the formation of small red crystals of $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgI}_2$ during the cooling of a boiling and filtered soln. of mercuric iodide with potassium nitrate. It is stated by E. Riegel that the salt is decomposed into its components by water. By dissolving some mercuric iodide in the hot filtrate from the preceding salt, E. Riegel claimed to have made acicular crystals of $2\text{Hg}(\text{NO}_3)_2 \cdot 3\text{HgI}_2$, but K. Kraut failed to obtain any such salt.

Double salts.—H. L. Wells and H. P. Beardsley⁷ believed that **cæsium mercuric nitrate**, possibly $\text{CsNO}_3 \cdot \text{Hg}(\text{NO}_3)_2$, existed in a soln. of the component salts; but they did not succeed in its isolation. K. Klinger reported the formation of a basic salt, **calcium mercuric oxynitrate**, by allowing a hot sat. soln. of calcium nitrate to stand a long time in contact with red mercuric oxide. G. Städeler obtained white octahedral (cubic) crystals of **barium mercurous oxynitrate**, $2\text{BaO} \cdot 2\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5$, by mixing soln. of the component salts. The crystals are colourless if produced in soln. free from acid and in darkness; in light or in acidic soln. the crystals have a yellow colour, and they become greenish-brown. They can be recrystallized colourless from nitric acid soln. The crystals are decomposed by water which abstracts barium nitrate, and leaves a yellowish-green residue. The salt is very soluble in hot dil. nitric acid. The corresponding **strontium mercurous oxynitrate**, $2\text{SrO} \cdot 2\text{Hg}_2\text{O} \cdot 3\text{N}_2\text{O}_5$, was prepared in an analogous manner, and it is much more soluble than the corresponding barium salt.

A. Mailhe obtained blue plates or prisms of dihydrated **cupric mercuric oxynitrate**, $\text{CuO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, from a soln. of mercuric oxide in a warm soln. of cupric nitrate; by working with cold. soln. he obtained blue plates of the tetrahydrate, $\text{CuO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$; and by adding yellow mercuric oxide to a conc. soln. of cupric nitrate, or by cooling a boiling soln. of mercuric oxide in a 4*N*-soln. of cupric nitrate, he obtained a blue powder consisting of quadratic prisms or plates of the pentahydrate, $\text{CuO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 5\text{H}_2\text{O}$. All the salts are readily decomposed by water with the separation of mercuric oxide. B. Finzi prepared pale blue acicular crystals of **cupric mercuric oxynitrate**, which he regarded as $\text{Cu}(\text{NO}_3)_2 \cdot \text{HgO} \cdot 3\text{H}_2\text{O}$, by cooling a filtered soln. obtained by boiling mercuric oxide in an almost sat. soln. of cupric nitrate. The crystals can be preserved unchanged in a desiccator; they lose water at 100° ; they are decomposed by water with the separation of mercuric oxide; they are soluble in nitric, sulphuric, and hydrochloric acids. The aq. soln. gives the characteristic reactions of mercuric and cupric salts, and when treated with potassium hydroxide, it becomes green without the separation of mercuric or cupric oxide. The addition of aq. ammonia forms an intense blue soln., and a white powder of ammonium mercuric nitrate. B. Finzi also prepared needle-like crystals of **silver mercuric oxynitrate**, $\text{AgNO}_3 \cdot 2\text{HgO}$, in a similar way. The crystals turn black on exposure to light; they are decomposed by water; they are soluble in nitric or sulphuric acid; with sodium thiosulphate, silver and mercuric thiosulphates, sodium nitrate, and sodium hydroxide are formed; mercuric iodide produces silver and mercuric iodides, and potassium nitrate and hydroxide. J. J. Berzelius reported columnar crystals of $2\text{AgNO}_3 \cdot \text{Hg}(\text{NO}_3)_2$, soluble in water without decomposition; and P. C. Ray obtained a series of silver mercuric oxynitrates with $(\text{Hg}, \text{Ag}) : \text{Hg} : \text{NO}_3$ in the ratios 4:1:2; 4:1:—; 7:1:8; 2:1:2; and 1·8:1:1·7, by rubbing mercurous nitrite with silver nitrate and the least possible quantity of water to form a mush, treating the mass with water, and evaporating the filtered soln. under reduced press. Lemon-yellow microscopic crystals are formed.

A. Mailhe prepared white quadratic crystals of **monohydrated zinc mercuric oxynitrate**, $\text{ZnO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$, by cooling a hot soln. of mercuric oxide in a conc. soln. of zinc nitrate; and acicular or monoclinic prisms of the dihydrate, $\text{ZnO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, by adding zinc oxide to a conc. soln. of zinc nitrate. Water decomposes both salts with the separation of mercuric oxide. He also obtained white hexagonal prisms of **dihydrated cadmium mercuric oxynitrate**, $\text{CdO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, by cooling a hot soln. of mercuric oxide in a conc. soln. of cadmium nitrate; and white monoclinic prisms or plates of the trihydrate, $\text{CdO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$, from a soln. of mercuric oxide in a soln. of cadmium nitrate. Both salts are decomposed by water.

§ 36. Ammonium Mercuric Compounds

According to A. F. de Fourcroy¹ (1792), a soln. of mercuric nitrate gives a white precipitate with ammonium nitrate, and on evaporating the filtered soln., six-sided crystals appear. L. Pesci prepared colourless crystals of **mercuric diamminonitrate**, $\text{Hg}(\text{NH}_3)_2(\text{NO}_3)_2$, by the action of a 50 per cent. soln. of ammonium nitrate upon the so-called Mitscherlich's salt—*vide infra*—or on a mercuric monoxynitrate, $\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2$. D. Strömholm also made plate-like crystals by mixing 6 grms. of mercuric nitrate dissolved in 2 c.c. of 4*N*- HNO_3 with enough water to make 10 c.c.; and then added 11 c.c. of 8 per cent. aq. ammonia, and 50 c.c. of 50 per cent. ammonium nitrate. L. Pesci formulated the salt $3\text{NH}_4\text{NO}_3 \cdot \text{NH}_2\text{Hg}_2\text{NO}_3$, **ammonium dimercuriammonium nitrate**; E. C. Franklin regarded it as the diammino-salt. The

crystals are not changed by exposure to light, with cold water the salt forms $\text{NH}_4\text{NO}_3 \cdot 3\text{NHg}_2\text{NO}_3 \cdot 2\text{H}_2\text{O}$, and with boiling water ammonium mercuric nitrate; it is soluble in aq. ammonia, and the soln. on evaporation furnishes $\text{NH}_4\text{NO}_3 \cdot \text{NHg}_2\text{NO}_3 \cdot \text{H}_2\text{O}$.

D. Strömholm mixed 6 grms. of mercuric nitrate dissolved in 2 c.c. of 4N- HNO_3 , and diluted with water to 10 c.c., with 11 c.c. of 8 per cent. aq. ammonia and 50 c.c. of 10–20 per cent. soln. of ammonium nitrate. The small octahedral crystals have the composition of **monomercuriammonium nitrate**, $\text{NH}_2\text{Hg} \cdot \text{NO}_3$ —the nitrate corresponding with infusible white precipitate, $\text{NH}_2\text{Hg} \cdot \text{Cl}$. When treated with warm water they form the nitrate of Millon's base.

The ammonio-base, **dimercuriammonium nitrate**, $\text{Hg}_2\text{N} \cdot \text{NO}_3$, was prepared by L. Pesci and C. F. Rammelsberg by the action of dil. nitric acid on Millon's base, while L. Pesci, and K. A. Hofmann and E. C. Marburg prepared it by the action of a slight excess of aq. ammonia on an aq. soln. of mercuric nitrate. L. Pesci also obtained it by washing mercuric diamminonitrate with hot water. C. F. Rammelsberg made it by heating mercuric oxide with a soln. of ammonium nitrate; and D. Strömholm by shaking monomercuriammonium nitrate with warm water. The salt is a pale yellow powder, insoluble in water, and yields no ammonia when boiled with potassium hydroxide. P. C. Ray could not obtain the anhydrous compound; but what was regarded as a hemihydrate, $\text{NHg}_2\text{NO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, was shown by E. C. Franklin to be more probably the monohydrate, *i.e.* the nitrate of Millon's base; it is also called Soubeiran's salt, is **mercuric hydroxyamidonitrate**, $\text{HO} \cdot \text{Hg} \cdot \text{NH} \cdot \text{Hg} \cdot \text{NO}_3$, or, according to K. A. Hofmann and E. C. Marburg, *oxydimercuriammonium amidonitrate*; $\text{OHg}_2 : \text{NH}_2\text{NO}_3$. P. C. Ray prepared his hemihydrate as a white amorphous powder by the action of conc. nitric acid on dimercuriammonium nitrite, NHg_2NO_2 ; and, according to E. Soubeiran and R. J. Kane, by adding a slight excess of dil. aq. ammonia to a soln. of mercuric nitrate containing the least possible quantity of acid. K. A. Hofmann and E. C. Marburg made the monohydrate by digesting Millon's base with 10 per cent. nitric acid; washing with water acidified with less and less nitric acid, then with alcohol, and ether; and finally drying in vacuo. H. Fürth made it by the action of ammonium nitrate on mercuric acetamide; or by the action of dil. nitric acid on the precipitate obtained by adding aq. ammonia to mercuric acetamide. R. J. Kane obtained it by boiling mercuric monomercuriammonium hydroxyamidonitrate with water. The white powder was found by E. Soubeiran, and R. J. Kane to become yellow when heated; it then gives off ammonia, nitrogen, and nitrous fumes; and finally oxygen and mercury; it is not decomposed, nor is ammonia evolved when it is boiled with potassium hydroxide; with hydrogen sulphide it forms mercuric sulphide and a neutral soln. of ammonium nitrate; nitrous fumes are given off when it is boiled with hydrochloric acid, but it is soluble in the cold acid, and reprecipitated by water; and it is sparingly soluble without decomposition in nitric and sulphuric acids. It is soluble in aq. ammonia and partially precipitated when water is added. P. C. Ray found his product to be sparingly soluble in nitric acid, and to detonate suddenly when heated in a tube, forming nitrous fumes, mercury, steam, and a reddish-yellow residue principally mercuric oxide. According to L. Pesci, E. Soubeiran's *protonitrate ammoniacomercuriel* is probably a mixture of Soubeiran's salt and mercury.

The so-called *Mitscherlich's salt* was obtained by C. G. Mitscherlich by treating a soln. of mercuric nitrate, acidified with as little nitric acid as possible, with dil. ammonia, not in excess, and drying at 100° ; he also obtained it by boiling the basic nitrate $2\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2$ with a soln. of ammonium nitrate. L. Pesci also obtained it by the action of water on mercuric diamminonitrate. L. Pesci represents the formula as $\text{NH}_4\text{NO}_3 \cdot 3\text{NHg}_2\text{NO}_3 \cdot 2\text{H}_2\text{O}$, *dihydrated ammonium-dimercuriammonium nitrate*; it has also been represented as *mercuriammonium oxydimercuriammonium nitrate*, $\text{NH}_2\text{Hg} \cdot \text{NO}_3 \cdot \text{NH}_2(\text{HgOHg})\text{NO}_3$; while E. C. Franklin regards it as **mercuric monomercuriammonium hydroxyamidonitrate**, $\text{NH}_2\text{Hg} \cdot \text{NO}_3 \cdot \text{HOHg} \cdot \text{NH} \cdot \text{Hg} \cdot \text{NO}_3$. The white powder behaves like Soubeiran's salt when heated, and when treated with

potassium hydroxide; according to R. J. Kane, when heated with water, it forms Soubeiran's salt; and, according to L. Pesci, when boiled with water, it forms dimercuriammonium nitrate. It is decomposed when heated to 100° , and is readily soluble in a soln. of ammonium nitrate. The salt was analyzed by M. C. Lea, L. Pesci, C. G. Mitscherlich, R. J. Kane, and J. S. F. Pagenstecher.

A compound with the empirical composition $\text{Hg}_2\text{N}_2\text{H}_6\text{O}_2\text{NO}_3$, was prepared by C. G. Mitscherlich by evaporating a soln. of Mitscherlich's salt or Soubeiran's salt in one of ammonium nitrate until crystallization occurs; J. C. F. Meyer made it by evaporating the soln. formed by adding a soln. of ammonia or ammonium carbonate to one of mercuric nitrate until the precipitate first formed is redissolved; L. Pesci also obtained it by super-saturating a dil. soln. of mercuric nitrate with ammonia—a similar process gave J. S. F. Pagenstecher a more basic product, *vide infra*. L. Pesci represented the composition by the formula $\text{NH}_2\text{HgNO}_3 \cdot \text{NH}_4\text{NO}_3 \cdot \text{H}_2\text{O}$; *hydrated ammonium dimercuriammonium nitrate*; it can also be regarded as *oxymmercuriammonium diamminonitrate*, $(\text{NH}_3)_2(\text{HgOHg})(\text{NO}_3)_2$; and E. C. Franklin represents it as *hemihydrated mercuric amidonitrate*, $\text{NH}_2\text{Hg} \cdot \text{NO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$, or as *mercuric diamminoxynitrate*, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{NH}_3 \cdot \text{HgO}$. L. Pesci found that the yellowish octahedral crystals lose very little water at 115° – 120° , but are decomposed at a higher temp. C. G. Mitscherlich said that the compound is easily decomposed by alkali hydrosulphides, and by hydrochloric acid, but not by other acids—sulphuric acid has no action, and the salt is very slightly soluble in nitric acid; soln. of ammonia and potassium hydroxide are without action, and it is decomposed with difficulty by baryta water.

G. C. Wittstein found that mercuric oxide dissolves in a large excess of a soln. of ammonium nitrate, forming a compound which is not precipitated by ammonia; mercurous oxide behaves in a similar way, but with the separation of mercury. R. J. Kane prepared what is known as *Kane's salt* by dissolving Soubeiran's salt, or mercuric oxide in a boiling soln. of ammonium nitrate, and on allowing the soln. to cool, small shining needles are obtained; he made the same salt by boiling mercuric nitrate with a soln. of ammonium nitrate. L. Pesci prepared the same salt, and represented its composition by $2\text{NH}_4\text{NO}_3 \cdot \text{NH}_2\text{HgNO}_3 \cdot 2\text{H}_2\text{O}$, or *dihydrated diammonium dimercuriammonium nitrate*; or as *hydrated diammonium oxymmercuriammonium nitrate*, $2\text{NH}_4\text{NO}_3 \cdot \text{NH}_2(\text{HgOHg})\text{NO}_3 \cdot \text{H}_2\text{O}$; or by E. C. Franklin, as *dihydrated mercuric monomercuriammonium diamminonitrate*, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{NH}_3 \cdot 2\text{H}_2\text{O} \cdot \text{NH}_2\text{HgNO}_3$. R. J. Kane stated that water extracts ammonium nitrate from the crystals and leaves the salt $\text{NH}_2(\text{HgOHg})\text{NO}_3$; and L. Pesci, that when heated to 110° – 115° , it loses a mol. of water, forming *monohydrated diammonium dimercuriammonium nitrate*, $2\text{NH}_4\text{NO}_3 \cdot \text{NH}_2\text{HgNO}_3 \cdot \text{H}_2\text{O}$; which E. C. Franklin represents as *monohydrated mercuric monomercuriammonium diamminonitrate*, $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O} \cdot \text{NH}_2\text{HgNO}_3$.

J. S. F. Pagenstecher and R. J. Kane obtained a pale yellow precipitate of *oxytrimercuriammonium nitrate*, $\text{NH}_2(\text{HgO} \cdot \text{HgO} \cdot \text{Hg})\text{NO}_3$, by adding a very large excess of ammonia to a soln. of mercuric nitrate. E. C. Franklin represented the product by the formula $\text{HgO} \cdot \text{HOHg} \cdot \text{NH} \cdot \text{HgNO}_3$, *mercuric oxyhydroxyamidonitrate*—but he believed that *Pagenstecher's salt* is really a mixture of two salts.

C. H. Hirzel prepared a white earthy powder with a composition corresponding with $\text{NHg}(\text{HgO} \cdot \text{HgO} \cdot \text{Hg})\text{HgNO}_3$, *mercuric oxytrimercuriammonium nitrate*; which E. C. Franklin symbolized $4\text{HgO} \cdot \text{Hg}(\text{NO}_3)_2 \cdot 2\text{NHg}_2\text{NO}_3$, *mercuric dimercuriammonium tetroxynitrate*. He rubbed 9 mols. of freshly precipitated mercuric oxide with a conc. soln. of 4 mols. of ammonium nitrate; then heated the mixture to the b.p., filtered rapidly, washed with boiling water, and dried the product. L. Pesci used a 40 per cent. soln. of ammonium nitrate and obtained dimercuriammonium nitrate. He was unable to make C. H. Hirzel's product. According to C. H. Hirzel, the product becomes yellow when heated, then decomposes suddenly with a hissing noise; there is an evolution of red nitrous fumes, and the sublimation of a reddish-brown substance—very little water is produced. A boiling soln. of potassium hydroxide colours it yellow, and ammonia is evolved; baryta water acts slowly, and all the nitrogen is gradually evolved as ammonia; it is insoluble in nitric acid; it gradually dissolves in a hot conc. soln. of ammonium nitrate, and with hydrochloric acid, a voluminous white precipitate is formed which dissolves when the mixture is warmed.

P. C. Ray reported a salt with the empirical formula $\text{Hg}_2\text{N}_2\text{H}_4\text{O}_2\cdot 2\text{NO}_3$, to be produced by the action of nitric acid on dimercuriammonium nitrite, $\text{Hg}_2\text{N}_2\text{O}_2$. E. C. Franklin regarded it as mercuric dimercuriammonium hydroxyamidonitrate, $\text{Hg}_2\text{NO}_3\cdot\text{HOHg}\cdot\text{NH}\cdot\text{HgNO}_3$.

H. Saha and K. N. Choudhuri obtained a white amorphous powder with the empirical formula $\text{N}_2\text{Hg}_2\text{H}_4\text{O}_5$, which can be rearranged $\text{NH}_4\text{NO}_3\cdot 2\text{HgO}$, mercuric ammonium oxynitrate, by adding an excess of aq. ammonia to mercurous nitrate, evaporating the filtered soln. in vacuo over conc. sulphuric acid, washing with distilled water, and drying over calcium chloride. The product does not lose weight on the water-bath; but when heated in a tube it decomposes explosively giving off nitrous fumes and ammonia. It is very stable, and is but slightly affected when boiled many days with a soln. of potassium hydroxide.

C. Barfoed obtained a product with the empirical formula $\text{HgO}\cdot 2\text{NH}_2\text{HgNO}_3$, mono-mercuriammonium oxynitrate, by adding a very slight excess of dil. aq. ammonia to a dil. feebly acid soln. of mercurous nitrate, and drying the washed product at 100° . It is soluble in acetic acid, and gives off ammonia when heated with a conc. soln. of potassium hydroxide. H. Saha and K. N. Choudhuri obtained the preceding compound by following C. Barfoed's instructions.

§ 37. Mercury Phosphates

C. F. Gerhardt¹ and P. L. Dulong found that when sodium hydrophosphate, Na_2HPO_4 , is added to a soln. of mercurous nitrate, a white crystalline precipitate of mercurous phosphate, Hg_3PO_4 , is produced. K. Haack dropped a cold soln. of one mol of mercurous nitrate into a cold soln. of a mol of sodium hydrophosphate, washed the precipitate with cold water, and dried it in air. If the mercurous nitrate be in excess, C. F. Gerhardt reported that mercurous nitratophosphate is produced, and K. Haack, a basic mercurous nitratophosphate. The following remarks by old observers may refer to mercurous phosphate or to the nitrate-phosphate. When the phosphate is heated in a tube, C. F. Gerhardt and P. L. Dulong found that it fuses and gives off mercury leaving a yellow glass of mercuric phosphate. The salt is said to be insoluble in water; R. Behrend measured the electromotive force of mercurous phosphate. H. Rose stated that when the salt is boiled with water, soluble mercuric phosphate and a grey mixture of mercury and the undecomposed salt are formed. According to J. B. Trommsdorff, hydrochloric acid colours the undecomposed salt grey, and black with a boiling soln. Aq. sulphurous acid or phosphorous acid slowly reduces the salt to mercury. The salt is said to be insoluble in an aq. soln. of phosphoric or tartaric acid and a cold soln. of potassium hydroxide decomposes the salt but no mercury passes into soln.; but a little mercury is taken up when the salt is decomposed by a hot soln. of potassium carbonate. R. H. Brett found the salt dissolves imperfectly in a soln. of ammonium chloride; G. C. Wittstein found that with an aq. soln. of ammonia or ammonium carbonate, the filtrate contains phosphoric acid and mercuric oxide, and a residue with mercury, mercurous and mercuric oxides, and ammonia.

J. Jacobsen prepared the double salt silver mercurous phosphate, AgHg_2PO_4 , by adding a soln. containing a mol of sodium hydrophosphate to a mixed soln. with one mol of silver nitrate, and two mols of mercurous nitrate acidified with 2 per cent.

of nitric acid. The yellowish-white rhombic prisms or plates are blackened by ammonia with the liberation of some mercury.

C. F. Gerhardt reported monohydrated **mercurous nitratophosphate**, $\text{HgNO}_3 \cdot \text{Hg}_3\text{PO}_4 \cdot \text{H}_2\text{O}$, to be formed when an excess of sodium hydrophosphate is poured into an acid soln. of mercurous nitrate; the precipitate at first disappears as soon as formed, but is afterwards permanent; it is then washed with cold water. The white or yellowish-white powder consists of minute plates. When heated in a tube it gives mercuric oxide and red fumes. According to C. F. Gerhardt, if the mercurous nitrate soln. be poured into an excess of one of sodium hydrophosphate, the amorphous precipitate is normal mercurous phosphate. K. Haack reported a pale yellow basic salt—**mercurous oxynitratophosphate**, $\text{Hg}_2\text{O} \cdot 2\text{HgNO}_3 \cdot 5\text{Hg}_3\text{PO}_4 \cdot \text{H}_2\text{O}$ —to be formed when a cold soln. with one mol of sodium hydrophosphate is dropped into one with 9 mols of mercurous nitrate, and the product washed with cold water, and dried in air—*vide supra*.

A white precipitate of **mercurous pyrophosphate** is obtained when sodium or ammonium pyrophosphate is added to a soln. of a mercurous salt. According to H. Rose, however, when the two salts are triturated with cold water, a blackish precipitate is obtained, and a mercurous salt free from mercuric compounds passes into soln., but with boiling water, the precipitate is blacker still, and the soln. contains both mercurous and mercuric phosphates. According to A. Schwarzenberg, the white precipitate indicated above is a crystalline powder which leaves a residue of mercuric metaphosphate when ignited. F. Stromeyer said that mercurous pyrophosphate is soluble in an excess of the sodium pyrophosphate, but L. Gmelin said that it is neither blackened nor dissolved by an excess of the sodium salt. A. Schwarzenberg found that when freshly precipitated the salt is soluble in the soln. of sodium pyrophosphate, but when dried at 100° , mercurous pyrophosphate is insoluble in that menstruum; and when the mixture is boiled, the mercurous pyrophosphate blackens. He also found that the salt is decomposed by hydrochloric acid, is dissolved by nitric acid. T. Brooks stated that mercurous oxide is decomposed in the dark by a cold soln. of sodium pyrophosphate, and the resulting salt—possible **mercurous pyrophosphate**—is very unstable and blackens with hot water.

According to C. G. Lindbom, a pale yellow amorphous precipitate of **mercurous oxytrimetaphosphate**, $\text{Hg}_3\text{P}_3\text{O}_9 \cdot \text{Hg}_2\text{O}$, is obtained by mixing soln. of mercurous nitrate and of sodium trimetaphosphate. H. Lüderer added sodium hexametaphosphate to one of mercurous nitrate and obtained a white precipitate which, when washed with water and dried at 100° , corresponded with **mercurous hexametaphosphate**, $\text{Hg}_6\text{P}_6\text{O}_{18}$. The precipitate is soluble in an excess of the precipitant, and it is insoluble in water but soluble in acids.

According to H. Rose, and K. Haack, sodium hydrophosphate precipitates white **mercuric phosphate**, $\text{Hg}_3(\text{PO}_4)_2$, from a strongly acidified soln. of mercuric nitrate; with mercuric sulphate, no precipitation occurs, and with mercuric chloride a precipitate is very slowly formed in the cold, and a compact red precipitate is rapidly formed in hot soln. If an excess of sodium hypophosphate is used the precipitate is yellow and the colour gradually turns brown. Mercuric cyanide soln. are not precipitated by sodium hypophosphate. K. Haack also obtained the salt by dropping phosphoric acid into an excess of a soln. of mercuric nitrate, and also by boiling basic mercuric sulphate with a soln. of sodium pyrophosphate, and extracting the mercuric oxide with acetic acid. C. F. Gerhardt obtained normal mercuric phosphate by feebly calcining the mercurous salt.

The white precipitate, said J. B. Trommsdorff, and C. F. Gerhardt, is crystalline; and K. Haack obtained it in small lustrous needles by cooling hot soln. The salt assumes a transient yellow colour when heated, and the air-dried salt loses no water at 100° . J. B. Trommsdorff added that the salt sinters together when heated, and fuses into a yellow glass; if heated more strongly, it gives off mercury, oxygen, and phosphorous oxide. G. C. Wittstein found the salt to be insoluble in water

and in alcohol, but K. Haack said that the salt is soluble in hot water. A. Barillé found the salt to be soluble in an aq. soln. of carbon dioxide. K. Haack could not prepare a *basic salt* by boiling the basic sulphate with an excess of sodium hydrophosphate soln., for the sulphuric acid was completely removed and a mixture of normal mercuric phosphate and mercury was produced. L. Gmelin said that mercuric phosphate dissolves in phosphoric acid; but K. Haack contradicted this statement. J. von Liebig found that phosphorous or sulphurous acid reduces the salt to mercury—the reaction is slow and incomplete. According to J. B. Trommsdorff, cold dil. hydrochloric acid dissolves the salt slowly, while the hot dil. acid dissolves it rapidly; the cold conc. acid also dissolves the salt rapidly and copiously with the evolution of heat. When the hydrochloric acid soln. is treated with stannous chloride, mercury and stannic phosphate are formed; and on evaporating the hydrochloric acid soln. to dryness, hot alcohol extracts mercuric chloride from the product—hence, hydrochloric acid abstracts mercuric oxide from phosphoric acid. A soln. of hydrochloric acid abstracts the phosphoric acid, and a soln. of potassium hydroxide also extracts all this acid from mercuric phosphate without dissolving mercuric oxide; while a soln. of potassium carbonate takes up part of the acid, and at the same time dissolves some mercury oxide which is not precipitated when the soln. is boiled. According to J. von Liebig, mercuric phosphate redissolves when sodium chloride is added to the mother liquid in which it has been formed, but the crystalline salt dissolves with difficulty. K. Haack found that the solubility in a soln. of sodium or potassium chloride is limited by the conc. of the nitric acid liberated during the reaction, and if the acid is removed, the precipitate is converted into a basic chloride. G. C. Wittstein found that aq. ammonia extracts from the salt a little mercuric oxide and phosphoric acid, the salt is also soluble in soln. of ammonium carbonate, sulphate, or nitrate; and J. B. Trommsdorff found one part of the salt dissolves completely in a hot soln. of six parts of ammonia, and the soln. reddens litmus. T. Brooks obtained **mercurosic oxyphosphate**, $7\text{Hg}_2\text{O} \cdot 14\text{HgO} \cdot 2\text{P}_2\text{O}_5 \cdot 20\text{H}_2\text{O}$, by the action of a conc. warm, but not boiling, soln. of sodium hydrophosphate on powdered mercurosic nitrate, and washing the product with cold water. The salt blackens superficially when exposed to the air; it does not lose water at 100° , but is completely decomposed at a higher temp.

According to A. Schwarzenberg, a soln. of mercuric nitrate gives a white or yellowish-red precipitate with sodium pyrophosphate. When dried at 100° , the composition is that of **mercuric pyrophosphate**, $\text{Hg}_2\text{P}_2\text{O}_7$. A. Reynoso obtained a basic chloride by boiling a soln. of mercuric chloride with sodium pyrophosphate. Mercuric pyrophosphate is insoluble in an excess of the sodium salt; it is soluble in acids; decomposed by potassium hydroxide; and dissolves in an aq. soln. of sodium chloride like mercuric phosphate. T. Fleitmann and W. Henneberg found sodium trimetaphosphate gave a slowly forming precipitate with mercuric nitrate—presumably **mercuric trimetaphosphate**. F. Warschauer heated mercuric oxide or mercuric nitrate with an excess of phosphoric acid to 400° , and obtained what was thought to be **mercuric tetrametaphosphate**. According to H. Rose, sodium hexametaphosphate gave a white precipitate or oily mass with mercuric nitrate, but not with mercuric chloride. P. Glühmann said that a conc. soln. of mercuric chloride gives a turbidity with soln. of sodium triphosphate, and when shaken with an excess of the latter, an amorphous powder is obtained which in a few days appears to be strewn with black crystals—possibly **sodium mercuric triphosphate**. According to H. Lüdert, the product is **mercuric hexametaphosphate**, $\text{Hg}_3\text{P}_6\text{O}_{18}$. The oily mass when dried in air forms a colourless translucent glass which after trituration and drying at 100° , appears like glue. The undried fresh precipitate is soluble in water, but the dried precipitate is but sparingly soluble. It is readily soluble in acids.

P. C. Ray² prepared a white crystalline powder of what he regarded as *dimercuriammonium hydrophosphate*, $\text{NHg}_2 \cdot \text{H}_2\text{PO}_4$, and E. C. Franklin as **mercuric**

monomercuriammonium phosphate, $\text{NH}_2\text{Hg.HgPO}_4$, by heating dimercuriammonium nitrite with phosphoric acid for 2–3 days at $50^\circ\text{--}60^\circ$, washing, and drying in the steam-bath. C. H. Hirzel digested freshly precipitated mercuric oxide with a soln. of ammonium hydrophosphate for some days in the cold, or for a less time when warmed, and obtained a white powder of what he regarded as *mercuric oxymercuriammonium phosphate*, $\text{Hg}\{\text{NH}_2(\text{HgOHg})\}\text{PO}_4$; C. F. Rammelsberg, as *mercuric oxyamidophosphate*, $\text{NH}_2\text{Hg.PO}_4:\text{Hg.HgO}$; and E. C. Franklin, as *mercuric hydroxyamidophosphate*, $\text{Hg}:\text{PO}_4\text{Hg.NH.HgOH}$. It is stable in air; it becomes yellow when heated and the white colour is restored on cooling; it melts at a higher temp. and decomposes with the evolution of water, ammonia, and mercury vapour, and if the decomposition is not complete, a glassy mass remains on cooling. It gives no ammonia when boiled with a soln. of potassium hydroxide; the nitrogen is all given off when treated with a soln. of potassium iodide or sulphide; it is decomposed by nitric acid and part is dissolved; and it is soluble in hydrochloric acid and a hot soln. of ammonium hydrophosphate. By heating Millon's base with phosphoric acid, C. F. Rammelsberg obtained a yellow compound which became grey on exposure to light, and which he regarded as *decahydrated monomercuriammonium oxymercuriammonium phosphate*, $2\text{NH}_2\text{OH}(\text{NHg}_2)_3\text{PO}_4.10\text{H}_2\text{O}$; but E. C. Franklin regarded it as a mixture of unchanged Millon's base with Ray's salt—*vide supra*.

§ 38. Ammonium Amalgam

In 1808, immediately after H. Davy's announcement of the discovery of potassium and sodium, T. J. Seebeck¹ placed mercury in a cavity cut in a piece of ammonium carbonate resting on a metal plate; the latter was placed in connection with the positive pole, and the mercury with the negative pole of a battery. The mercury swelled up into a frothy mass, with the consistency of butter. The product is considered to be ammonium amalgam. Almost simultaneously, J. J. Berzelius and M. M. Pontin passed a current through a conc. aq. soln. of ammonium chloride, in such a way that the cathode dips into mercury, and obtained a similar frothy product. In place of T. J. Seebeck's ammonium carbonate, H. Davy, and J. B. Trommsdorff used ammonium chloride, and J. L. Gay Lussac and L. J. Thénard, the sulphate or phosphate, and showed that the salt itself could be connected directly with the positive pole of the battery. In any case, oxygen is evolved at the positive

pole, though with ammonium chloride, chlorine is also given off; very little is gas given off at the cathode. A convenient apparatus for the purpose is shown in Fig. 41.

FIG. 41.—The Preparation of Ammonium Amalgam.

According to G. Michaud, the use of an amalgam of mercury with other metals—silver, gold, aluminium, bismuth, lead, etc.—in place of mercury alone, lowers the stability of the resulting ammonium amalgam, and this the more the greater the electropositive character of the metal. Thus, C. M. Wetherill found that a small amount of platinum altogether inhibits the formation of ammonium amalgam. H. Landolt, and J. Schröder employed an analogous process, and found that the greater the surface of contact with the ammonium chloride soln., the better the yield. H. Moissan electrolyzed a soln. of ammonium mercuric iodide, $(\text{HN}_4)_2\text{HgI}_4$ in liquid ammonia, or an aq. soln. of ammonium iodide, mercuric iodide and water, at -40° . S. von Laszcynsky electrolyzed a soln. of ammonium thiocyanate with a mercury cathode, using a current of 0.5 amp. and 7 volts.

H. Davy prepared ammonium amalgam by placing a little mercury containing about one per cent. of sodium potassium, or barium in moistened ammonium salt, in aq. soln., or a soln. in conc. aq. ammonia. F. S. Pfeil and H. Leffman state that if the ammonium salt is dry, no reaction occurs; but in the presence of moisture, the mercury swells up, forming the amalgam. A. Coehn found amalgams of potassium, sodium, lithium, and strontium furnished ammonium amalgam, but he was not successful with barium and magnesium amalgam. W. Kettembeil used alkali amalgams with a conc. aq. soln. of ammonium chloride. R. Böttger found sodium amalgam to be more effective than potassium amalgam. J. Proude and W. H. Wood inferred that soln. of ammonium salts in phenol, or in a soln. of pyrogallol in aq. ammonia, contained compounds of the nature of ammonium salts. C. M. Wetherill obtained ammonium amalgam by the action of sodium amalgam on a soln. of methylamine oxalate free from ammonia, and F. S. Pfeil and H. Leffman likewise with a sat. soln. of trimethylamine ammonium chloride; but not with sodium amalgam and a sat. soln. of the hydrochloride of aniline, conine, morphine, or quinine, or of rosaniline acetate. H. Moissan prepared ammonium amalgam by placing a little dry ammonium iodide or chloride in liquid ammonia, and shaking the mixture at about -35° with sodium amalgam; the product is washed with liquid ammonia to remove the ammonium and sodium iodides; and then cooled with ether to -80° . J. J. Berzelius and M. M. Pontin stated that ammonium amalgam has the consistence of butter and the colour of mercury. As shown by K. W. G. Kastner, the amalgam prepared by the electrolytic process is often crystalline. H. Davy said that the amalgam formed below 0° crystallizes in cubes, and W. R. Grove found that when cooled by a mixture of solid carbon dioxide and ether, the amalgam becomes brittle, and exhibits a dark grey, faintly lustrous fracture. J. J. Berzelius found the amalgam to be lighter than water, and J. Proude and W. H. Wood added that the sp. gr. of well-formed mercury froth is not greater than 0.730 since it floats on ether of that sp. gr. The amalgam soon decomposes into liquid mercury and a mixture of approximately 1 vol. of hydrogen and 2 vols. of ammonia. J. J. Berzelius and M. M. Pontin stated that the amalgam decomposes as soon as it is taken out of the voltaic circuit, but that which is prepared with potassium or sodium remains undecomposed a longer time because it retains a small proportion of these elements; it resists decomposition longest in an atm. of hydrogen. According to H. Davy, the decomposition in air or water is not accompanied by the absorption of oxygen or the formation of ammonium carbonate, although in dil. sulphuric acid, mercury, ammonium sulphate, and sulphur are formed; and in hydrogen chloride, ammonium chloride, mercury, and hydrogen. The action

of various impurities in the mercury on the decomposition of the amalgam, and the action of the amalgam on various salt soln., *vide infra*. L. P. Cailletet found that ammonium amalgam is decomposed by a plate of iron, platinum, or aluminium; and that agitation with sodium amalgam, in the presence of water, has a similar effect. H. Davy found that the amalgam also decomposes under fixed oil, and J. L. Gay Lussac and L. J. Thénard stated that the decomposition is accelerated by agitating the amalgam alone or with mercury, also by contact with rock oil, and still more so by contact with alcohol or ether. The decomposition of the amalgam is attended by the inflation of the mercury into a kind of froth. J. L. Gay Lussac and L. J. Thénard said that the mercury swells up to five times its original bulk: H. Davy, 8–10 times; R. Böttger, 20 times; and H. Moissan, 25 to 30 times. According to W. R. Grove, and C. F. Schönbein, the amalgam does not give off gas when cooled by a mixture of ether and solid carbon dioxide, but gas begins to be given off as the solid liquefies. H. Moissan found appreciable swelling occurs at -30° , and H. Davy said that at -29° the decomposition is as rapid as at ordinary temp. During the decomposition of the amalgam, the temp., under ordinary conditions, was found by H. Moissan to rise 5° or 6° ; G. Baborovsky and V. Vojtech found that during the decomposition of the amalgam, some positive ions are given off, without photographic action. When J. J. Berzelius and M. M. Pontin communicated their discovery to H. Davy in 1808, they stated that ammonia must be an oxide like potash and soda, and that the new substance was a compound of the metallic constituent of ammonia with mercury. H. Davy applied the term *ammonium* to the supposed metallic basis of ammonia. J. L. Gay Lussac and L. J. Thénard regarded the amalgam as a triple compound of mercury, ammonium, and hydrogen, and the latter afterwards called it *l'hydrure ammoniacal de mercure*. In 1816, A. M. Ampère said:

The difficulty in assimilating the constitution of ammoniacal to metallic salts would disappear if it be admitted that, just as cyanogen, although a compound body, exhibits all the properties of the simple bodies which are capable of acidifying hydrogen, so the combination of one volume of nitrogen and four volumes of hydrogen which is united to mercury in the amalgam discovered by T. J. Seebeck, and to chlorine in the ammonium chloride, behaves in all the compounds which it forms like the simple metallic substances.

This is virtually the present-day theory of the constitution of ammonium compounds, and was developed and extended by J. J. Berzelius. It was argued that the amalgam is a true soln. of ammonium in mercury, and that it readily decomposes into mercury, ammonia, and hydrogen when warmed above 0° , and these gases entangled with the mercury give it the appearance of a froth.

The gases obtained by the decomposition of ammonium amalgam have been analyzed by H. Davy, J. L. Gay Lussac and L. J. Thénard, H. Landolt, R. Routledge, H. Moissan, etc. The general results show that ammonia and hydrogen are present very nearly in the proportions required for the radicle NH_4 . Conflicting opinions were entertained about the amalgam. For example, J. F. Daniell regarded the amalgam as a mixture of gases and mercury resulting from the cohesion of the mercury and the adhesion to it of the gases, and he likened the action to the absorption of oxygen by molten silver. W. R. Grove regarded the amalgam as a chemical compound of mercury and nitrogen inflated by hydrogen. H. Moissan followed J. L. Gay Lussac and L. J. Thénard in assuming that ammonium amalgam is ammoniacal mercury hydride because when a soln. of sodium amalgam is allowed to stand with aq. ammonia, much swelling occurs with the formation of a buttery mass which maintains itself for 2 or 3 days in the ammoniacal soln., while if sodium amalgam alone is treated with the same liquid, hydrogen is slowly evolved with no inflation of the mass. G. McP. Smith extended these experiments to potassium, lithium, barium, strontium, and calcium amalgams; he found that all formed ammonium amalgam when treated with a soln. of ammonium chloride, and also that although there is no inflation with sodium amalgam, all the others do swell. According to C. M. Wetherill, the amalgam is not an alloy of mercury and ammonium; H. Landolt

concluded that while the amalgam contains the NH_4 -group in combination with mercury, it is not a veritable amalgam, because, unlike the amalgams of potassium and sodium, it does not react by double decomposition with soln. of salts of copper, silver, and iron. M. le Blanc showed that H. Landolt's failure to obtain double decompositions with ammonium amalgam and the salts of copper, silver, and iron does not disprove the metallic nature of ammonium in its amalgam, because, owing to its instability, ammonium has not the force necessary to displace metals from their compounds, but immediately decomposes on severing its union with mercury. A. Coehn further showed that when ammonium amalgam is brought in contact with a soln. of cupric sulphate at 0° , the copper is displaced from its soln.: $2(\text{NH}_4) + \text{CuSO}_4 = \text{Cu} + (\text{NH}_4)_2\text{SO}_4$; he also tried to reduce metals which are not reducible by hydrogen, and he succeeded in doing so with soln. of cadmium and zinc sulphates. This, said A. Coehn, should remove the last objection to the hypothesis that ammonium has the nature of a metal. The argument, however, is not decisive. According to M. le Blanc, atomic hydrogen can displace zinc under somewhat similar conditions, but potassium, barium, etc., are not reduced in this way. Hence, if ammonium amalgam be capable of displacing these elements from their salt soln., the displacement can be the result of an exchange with ammonium in the amalgam, and not a reduction of nascent hydrogen from the decomposition of the amalgam. G. MCP. Smith showed that ammonium, like the metals of the alkali and alkaline earth groups, is inversibly displacable in the form of its amalgams. C. A. Seely found that the volume of the inflated mass varied with the superimposed press., and argued that the amalgam is a soln. of gas in the mercury, and not an ammonium amalgam. A. H. Gallatin, G. W. Gunning, and W. Weyl, however, showed that the decomposition of ammonium amalgam gives hydrogen with properties of that gas *in statu nascendi*, and therefore inferred that the radicle ammonium exists in the amalgam. R. Routledge assumed that the NH_4 -radicle is combined with the mercury because the gases are present in the required proportions; and because the NH_4 is apparently diffused uniformly throughout the mass. He also found that the compressibility of the inflated mass agrees fairly well with the assumption that it contains a gas and mercury, and added:

We may admit that such a compound is originally formed, and decomposes rapidly into mercury, ammonia, and hydrogen, while the gases, becoming entangled in the mass, impart to it that remarkable turgescence, which is not, however, a property of the original compound, but merely an accidental result of its decomposition.

The swelling is not a characteristic property of the amalgam, but is a secondary phenomenon attending its decomposition, since below 0° the amalgam shows little tendency to inflation. G. Aronheim studied the electrical phenomenon attending the bubbling through the mercury of the gas from decomposing amalgam.

M. le Blanc found that when a soln. of an ammonium salt is electrolyzed with a mercury cathode, the polarization between the resulting amalgam and amalgamated zinc rises to a maximum in a few minutes, and that the maximum is nearly as high as is obtained by the similar treatment of a sodium salt. When the polarizing current is cut off, the inflated mercury cathode remains electronegative to the soln. for 10 to 20 mins. This effect is not due to the hydrogen, since the hydrogen polarization drops off almost as soon as the current is broken, while it resembles the effect obtained with amalgams of the alkali and alkaline earth salts. So that a metallic body analogous with potassium and sodium is combined with mercury in ammonium amalgam. The greater fall of potential in breaking the circuit with ammonium amalgam is due to the greater instability of the amalgam, and to its low NH_4 -content. A. Coehn and K. Dannenberg measured the potential necessary for the continuous evolution of hydrogen on a mercury cathode, and found it to be 1.52 volts; with the ammonium salts at 1.24 volts, the amalgam begins to form, and this is fully analogous with the results obtained with the alkali metals. H. C. Pocklington measured the e.m.f. of a Daniell's element in which the zinc was replaced by ammonium amalgam; and

hence inferred that the amalgam contains the free radicle which rapidly decomposes into ammonia, hydrogen, and mercury. According to F. M. G. Johnson and N. T. M. Wilsmore, the e.m.f. of ammonium amalgam in a *N*-soln. of ammonium nitrate in liquid ammonia, against cadmium in a sat. soln. of cadmium nitrate, is 0.91 volt.

E. M. Rich and M. W. Travers measured the depression of the f.p. of ammonium amalgam, and inferred that it is a soln. of ammonium in mercury; but G. McP. Smith also showed that the results also accord with the assumption that the amalgam is a soln. of a substance of the empirical composition NH_4Hg_n . H. Moissan obtained no evidence of the existence of free ammonium in the reactions between ammonium chloride and lithiumammine: $2\text{NH}_4\text{Cl} + 2\text{NH}_3\text{Li} = 2\text{LiCl} + 4\text{NH}_3 + \text{H}_2$; between hydrogen sulphide and lithiumammine: $\text{H}_2\text{S} + 2\text{NH}_3\text{Li} = \text{Li}_2\text{S} + 2\text{NH}_3 + \text{H}_2$; etc., in liquid ammonia at -100° ; nor did O. Ruff obtain any evidence of the formation of ammonium at -95° with a press. up to 60 atm. He passed a current through liquid ammonia with the electrodes surrounded by small lumps of potassium iodide, metallic potassium was liberated at the cathode, and rising to the upper layer of liquid ammonia, coloured it blue; when ammonium iodide was substituted for potassium iodide, no blue coloration occurred. He thus doubted if such a substance as NH_4 analogous to metallic potassium can be produced, and he regarded NH_4 as a compound H.NH_3 analogous with K.NH_3 , NaNH_3 , and Li.NH_3 . G. McP. Smith, however, argued that he has shown that alkali and alkaline earth metals exist in mercury, even in dil. soln., not in the form of single atoms, but in that of compounds of this general formula MHg_n , containing only one atom of the amalgamated metal per mol. Some of the so-called substituted ammoniums—in which one or more of the hydrogen atoms of NH_4 are replaced by one or more of the alkyl groups CH_3 , C_2H_5 , C_3H_7 , . . . —are more stable than ammonium amalgam. H. N. McCoy and W. C. Moore have prepared crystalline amalgams closely resembling those of potassium and rubidium. W. Palmaer also found that the electrolysis of soln. of the substituted ammonium salts in liquid ammonia gave a blue-coloured soln. about the cathode. The blue cathode liquid has the same colour as soln. of the alkali metals in liquid ammonia, although it is less stable, for it decolorizes in a short time. Hence, it is inferred that if ammonium or a substituted ammonium could be isolated in a free state, it would exhibit metallic properties resembling the alkali metals.

§ 39. Amalgams of the Alkali Metals

The solubility of the alkali metals in mercury increases with increasing temp. and with increasing at. wt. W. Kerp and co-workers¹ found for the percentage solubility:

	0°	25°	65°	100°
Lithium . . .	0.04	0.07	0.11	0.13
Sodium . . .	0.54	0.65	0.86	1.11
Potassium . . .	0.31	0.54	1.25	2.12
Rubidium . . .	0.92	1.37	—	—

W. Kerp and co-workers, and H. Winter also measured the solubility of sodium in mercury. T. W. Richards and R. N. G. Thomas found lithium is soluble in mercury only to the extent of 0.0036 per cent. G. McP. Smith and co-workers, and E. Maey also made observations on the solubility of lithium in mercury. The coeff. of diffusion, *k*, of the metals in mercury varies periodically with the at. wt. M. von Wogau found:

	Li	Na	K	Rb	Cs
$k \times 10^{-6}$. . .	7.63	7.41	6.02	5.32	5.21

H. Davy observed that mercury and potassium readily unite at ordinary temp. with the evolution of much heat; J. Schumann said that the union is accompanied by *lebhafter Feuererscheinung*, and, according to J. L. Gay Lussac and L. J. Thénard, *sans dégagement de lumière*. V. Merz and W. Weith said that sodium reacts at a rather lower temp., and more vigorously than potassium; J. L. Gay Lussac and L. J. Thénard said that the reaction between sodium and mercury is attended by *un grand dégagement de chaleur et de lumière*. G. S. Sérullas, indeed, stated that when a piece of sodium is projected on mercury, it may be thrown out of the vessel with an explosion owing to the great development of heat. The rapid gyratory movement which occurs when a piece of potassium or sodium is placed on mercury, depends on the absorption and decomposition of atm. moisture by the alkali metal; and the liberation of hydrogen gives rise to the motion; if the experiment be made in dry air, the amalgamation is tranquil—3.24 c.c. of gas per gram of sodium is given off during the formation of sodium amalgam—if the sodium used be purified in vacuo, L. Kahlenberg and D. Klein obtained no hydrogen.

The amalgams can be prepared by mixing the component metals. R. Böttger rubbed the two metals in a dry mortar fitted with a cover, and preserved the product under a layer of naphtha. G. McP. Smith added 15 grms. of sodium in small pieces at a time at ordinary temp. to one kgrm. of mercury; the temp. rose to 150°. The amalgam is then kneaded under water, and dried with filter paper. K. Bornemann and G. von Rauschenplat, C. Löwig, J. Schumann, W. Kerp and co-workers, H. Winter, A. Guntz and J. Férée, and M. Rosenfeld used a similar process. It is difficult to prepare directly amalgams of the alkali metals with a definite composition because, as M. Berthelot, and N. S. Kurnakoff pointed out, a part of the sodium is oxidized; in consequence, H. G. Byers, E. Jänecke, and M. Reuter worked in an atm. of hydrogen, and E. Vanstone in an atm. of carbon dioxide; J. Schumann melted the alkali metal under petroleum, and added the mercury to the metal; the temp. rose to the ignition point of the oil. Hence, O. Mühlhäuser added the mercury in a very thin stream. T. W. Richards and J. B. Conant prepared sodium amalgams by electrolysis:

A sat. soln. of pure sodium carbonate (four times recrystallized and centrifuged) was electrolyzed in a cell consisting of an ample mercury cathode and an anode of platinum foil; a wide-mouthed half-litre bottle served as the container. After passing a current of 4 ampères for a few hours, the amalgam became pasty and the process was stopped. The electrolyte was poured off as completely as possible and the amalgam was thoroughly agitated with 4 or 5 portions of distilled water and subsequently with 2 portions of alcohol. It was transferred to a small flask which was evacuated and heated for some minutes. Having been thus dried, it was placed while still hot in a desiccator, where it remained until it was diluted, and filtered through a capillary tube in order to eliminate the film of hydroxide.

A. Schüller, E. Maey, A. C. Vournasos, P. T. Muller, N. S. Kurnakoff, H. N. Draper, G. McP. Smith, G. N. Lewis and C. A. Kraus, L. Schüz and E. Vanstone mixed the metals under a layer of paraffin or petroleum oil; and M. Renter under a layer of xylol. The hydro-carbon is difficult to remove completely from the product. N. S. Kurnakoff and G. J. Zukowsky made cæsium amalgam by the direct union of the elements. E. Maey, G. McP. Smith, and G. J. Zukowsky also made lithium amalgam by the direct union of the elements. A. D. Hirschfelder and M. C. Hart prepared sodium amalgam in the form of fine flocculi by pouring hot liquid amalgam into a jar of xylene or kerosene agitated by an electrical stirrer. The amalgam was allowed to settle, and dried in a current of air.

There is a reversible displacement of the alkali metals in amalgams and in aq. soln. of their salts. For example, sodium amalgam in a soln. of potassium hydroxide was found by J. Schumann, G. McP. Smith, and W. Kettembeil, to form potassium amalgam. G. Fernekes, and G. McP. Smith obtained similar results with soln. of the alkali chlorides. The latter also found that potassium amalgam forms sodium amalgam in a soln. of sodium hydroxide or sodium chloride. Similarly also with lithium amalgam. P. Schorigin obtained sodium amalgam by the action of sodium ethide, NaC_2H_5 , on mercury: $2\text{C}_2\text{H}_5\text{Na} + 2\text{Hg} = 2\text{HgNa} + \text{C}_2\text{H}_4 + \text{C}_2\text{H}_6$. The reaction between mercuric diethyl and sodium does not proceed so smoothly.

The alkali metals are not always conveniently available for preparing amalgams, and in that case electrolytic methods are available. M. Reuter pointed out that judging from the records of these methods, however, the products nearly always have a low percentage proportion of the alkali metal; conc. amalgams have not been obtained. J. J. Berzelius and M. M. Pontin prepared potassium amalgam by placing mercury in a cup covered with a conc. soln. of potassium hydroxide; the mercury serves as negative electrode, a metal wire dipping in the soln. as positive electrode. On electrolysis, potassium amalgam is formed. J. Schumann, G. McP. Smith and H. C. Bennett, T. W. Richards and E. Müller, and R. Lüpke employed a similar process also involving the use of the mercury cathode. W. Kerp, G. Bird, G. McP. Smith and H. C. Bennett, and E. S. Shepherd, electrolyzed a soln. of potassium or sodium chloride with a mercury cathode; and S. von Laszcynsky, a soln. of potassium or sodium thiocyanate. W. Kerp and co-workers, and G. McP. Smith and H. C. Bennett made rubidium amalgam, and the latter also cæsium and lithium amalgam by the electrolysis of soln. of the chlorides with mercury as cathode. G. McP. Smith and J. R. Withrow electrolyzed soln. of lithium acetate or sulphate using a mercury cathode. A. Guntz and J. Férée, and K. Bornemann and G. von Rauschenplat made lithium amalgam by the electrolysis of soln. of the chlorides. E. Mitscherlich used a soln. of lithium hydroxide as electrolyte. The electrolytic method was modified by O. Arlt who allowed a stream of mercury to fall through a soln. of a salt of the alkali metal, and kept a protective layer of carbon disulphide or chloroform between the mercury layer and the electrolyte during the passage of the current. The method was employed by W. Nernst, W. Kerp and W. Böttger, J. R. Withrow, and P. M. Giesy and J. R. Withrow, E. C. Bain and J. R. Withrow. E. S. Shepherd suspended a mercury cathode in a porous cup at the surface of the sodium salt soln. being electrolysed; this avoided the insulating action of the specifically lighter amalgam which accumulates at the surface of the mercury. The method was employed by

G. McP. Smith and J. R. Withrow, S. B. Frank and J. R. Withrow, and P. M. Giesy and J. R. Withrow. S. B. Frank and J. R. Withrow prepared solid alkali amalgams by electrolysis.

The f.p. curve of the lithium amalgams, by G. J. Zukowsky,² is shown in Fig. 42; there is a eutectic at 162° between Li_3Hg and lithium, and the eutectic has 97 atomic per cent. of lithium; there is a bend in the curve at 275° and 83.6 atomic per cent. of lithium corresponding with the transition of Li_3Hg into what is possibly Li_3Hg_2 or Li_2Hg ; and at 406° and 65.3 atomic per cent. of lithium, this begins to decompose, forming LiHg . There is a maximum—dystectic—point at 600.5° with 50 atomic per cent. of lithium corresponding with the compound LiHg . The transformations at 338° and 30.1 atomic per cent. of lithium, and at 232° and 17.6 atomic per cent. of lithium respectively correspond with the formation of compounds LiHg_2 and LiHg_3 . There is a second eutectic at -42° with less than one per cent. of lithium. According to E. Maey, the sp. vol. curve shows singular points corresponding with **lithium hexamercuride**, LiHg_6 , and with **lithium pentamercuride**, LiHg_5 . A. Guntz and J. Féréé prepared the pentamercuride by the electrolysis of soln. of lithium

FIG. 42.—Freezing-point Curve of Lithium Amalgams.

chloride with a mercury cathode. E. Maey said that it forms six-sided, needle-like crystals. W. Kerp and co-workers found that the crystals melt over 100° , at 100° the crystals are mixed with liquid, and the two form a mobile mush at 125° , and all is melted at 165° . G. J. Zukowsky obtained needle-like crystals corresponding with **lithium trimercuride**, LiHg_3 ; E. Maey obtained evidence of this compound on the sp. vol. curve; and G. McP. Smith and H. C. Bennett isolated the crystals by centrifuging the mass. G. J. Zukowsky obtained a mass with needle-like crystals of **lithium dimercuride**, LiHg_2 ; and cubic crystals of **lithium monomercuride**, LiHg , of hardness 2 to 3. E. Maey obtained evidence of this compound on the sp. vol. curve. G. J. Zukowsky obtained a mass with needle-like crystals thought to be **lithium hemimercuride**, Li_2Hg , or **lithium ditritamercuride**, Li_3Hg_2 ; similarly also of **lithium tritamercuride**, Li_3Hg . Evidence of this latter compound on the sp. vol. curve was obtained by E. Maey. G. McP. Smith obtained crystals by filtering the electrolytically prepared amalgam through leather, and afterwards treating the product in a centrifuge. F. H. Newman studied the spectra of alkali amalgams.

The f.p. curve of the sodium amalgams is shown in Fig. 43. There is a maximum at 360° corresponding with NaHg_2 ; and A. Schüller interprets the rest of the curve as representing the formation of NaHg_4 at 159° ; $\text{Na}_{12}\text{Hg}_{13}$ at 227° ; of NaHg at 219° ; of Na_3Hg_2 at 125° ; of Na_5Hg_2 at 62° ; and of Na_3Hg at 34° . The f.p. curve of sodium and mercury was also studied by M. Berthelot, W. Kerp and co-workers, V. Merz and W. Weith, K. Bornemann, N. S. Kurnakoff, A. Gorboff, C. H. Desch, G. Tammann, P. I. Bachmetjeff and J. V. Wsharoff, E. Vanstone, E. Maey, D. Mazzotto, P. T. Muller, and L. Schüz. M. Berthelot assumed the existence of **sodium octomercuride**, NaHg_8 ; and A. Guntz and J. Féréé claim to have obtained it in crystals by cooling a 0.57 per cent. sodium amalgam to -19° , and separating the excess of mercury; and A. Joannis, by the slow action of mercury on a soln. of sodammonium in liquid ammonia. H. Winter, N. S. Kurnakoff, E. Maey, and G. Tammann studied **sodium hexamercuride**, NaHg_6 , K. Kraut and O. Popp prepared it by the action of a soln. of sodium hydroxide or carbonate on 3 per cent. sodium amalgam, and squeezing out the excess of mercury; W. Kerp and co-workers by crystallization from sodium amalgam sat. at 75° , and cooled to 25° ; and A. Guntz and J. Féréé by slowly cooling a soln. of sodium in mercury, and squeezing out the excess of mercury. The needle-like crystals were stated by the latter to belong to the cubic system. W. Kerp and co-workers said that they form a mush at 39° , and are all melted at 58° ; and form **sodium pentamercuride**, NaHg_5 , between 40° and 42° . G. P. Grimaldi believed that K. Kraut and O. Popp's $\text{Na}_2\text{Hg}_{12}$ is really the pentamercuride. W. Kerp's analyses of the compound, prepared at temp. ranging from 0° to 99.8° , have the mean value 2.13 per cent. Na. G. McP. Smith and H. C. Bennett's analyses varied from 2.12 to 2.28 per cent. Na. It is the richest solid sodium amalgam. W. Kerp obtained it from the amalgam at a temp. over 25° ; W. Kerp, W. Böttger, and H. Winter, above 100° ; G. P. Grimaldi, by centrifuging a 1.4 per cent. sodium amalgam; and A. Guntz and J. Féréé, by melting the hexamercuride and adding a rather richer amalgam; then heating the whole to 200° ; cooling to 140° , and decanting off the excess of mercury. The prismatic crystals were found by G. P. Grimaldi to melt at 145° , but, according to W. Kerp, fusion begins at about 105° , a thick mush is formed at 19° , and all is melted at 138° – 139° , and it is not stable above 105° . G. P. Grimaldi measured the electrical resistance, and W. Kerp, the solubility in 100 parts of mercury:

FIG. 43.—Freezing-point Curve of Sodium Amalgams.

NaHg_5 per cent.	0°	25°	40°	56.7°	81°	99.8°
	24.33	28.79	32.25	35.58	41.14	49.46

W. Kerp and co-workers obtained crystals corresponding with **sodium tetramercuride**, NaHg_4 , from sodium amalgam over 180° ; A. Guntz and J. Féréé, by squeezing the hexa- or penta-mercuride at 200 to 1200 kgrms. per sq. cm.; and A. Schüller, by melting an amalgam with 20 at. per cent. of sodium over 220° , and slowly cooling while it is being stirred. E. Vanstone obtained long prismatic crystals. W. Kerp doubted the existence of this as a chemical individual. M. Berthelot, and K. Bornemann also studied this compound. In his study of the f.p. curve, N. S. Kurnakoff obtained evidence of a compound Hg_nNa , where n is less than 5 and greater than 2, and by analogy with the corresponding potassium

compound he assumed it to be **sodium trimercuride**, NaHg_3 . A. Schüller obtained crystals of **sodium dimercuride**, NaHg_2 , by melting a 33.3 at. per cent. sodium amalgam above 360° . E. Jänecke gave 350° for the m.p. This compound has been studied by N. S. Kurnakoff, G. Tammann, E. Maey, M. Berthelot, K. Bornemann, and P. T. Muller. There are four doubtful compounds Hg_nNa with n between 1 and 2. N. S. Kurnakoff obtained evidence of one being formed by the decomposition of the monomercuride at 209.7° ; E. Maey and M. Berthelot, Na_4Hg_7 ; E. Vanstone, Na_7Hg ; and K. Bornemann and A. Schüller, $\text{Na}_{12}\text{Hg}_{13}$. N. S. Kurnakoff and A. Schüller obtained evidence of the existence of **sodium monomercuride**, NaHg , on the f.p. curve. E. Vanstone, M. Berthelot and E. Maey studied its properties. E. Jänecke found the prismatic crystals melted at 217° ; and N. S. Kurnakoff, that they decomposed at about 209.7° . E. Vanstone, K. Bornemann, and A. Schüller obtained crystals of **trisodium dimercuride**, Na_3Hg_2 . H. von Wartenberg found that Na_3Hg is stable in the vapour phase between 380° and 444° . N. S. Kurnakoff, and E. Maey also obtained evidence of the existence of a compound Na_nHg , when n is equal to or less than 2.5. A. Schüller, and K. Bornemann obtained evidence of **sodium dipentitamercuride**, Na_5Hg_2 , but E. Vanstone doubted if such a compound really exists. E. de Souza obtained **sodium tritamercuride**, Na_3Hg , by heating sodium amalgam with an excess of mercury to 400° . E. Vanstone, E. Maey, K. Bornemann, and G. Tammann studied this product.

E. Jänecke obtained the f.p. curve of potassium amalgams, Fig. 44, and found a maximum at 279° corresponding with KHg_3 , and the rest of the curve is interpreted to show the formation of K_2Hg at 178° ; HgK_3 or K_9Hg_3 at 204° ; K_2Hg_9 at 173° ; and KHg_9 or KHg_{10} at 70° . The f.p. curve has also been studied by M. Berthelot, V. Merz and D. Mazzotto, W. Weith, G. Tammann, N. S. Kurnakoff; W. Kerp, W. Böttger, and H. Winter, K. Bornemann, P. Müller, and E. Maey. Crystals of what A. Guntz and J. Féréé regarded as **potassium octodecamercuride**, KHg_{18} , were obtained by cooling an amalgam of the two metals to -19° . W. Kerp, W. Böttger, and H. Winter obtained **potassium tetradecamercuride**, KHg_{14} , from an amalgam by press. between -2° and -12° . E. Jänecke, K. Bornemann, and G. Tammann

FIG. 44.—Freezing-point Curve of Potassium Amalgams.

obtained evidence of the existence of a compound, **potassium enneamercuride**, KHg_9 , on the f.p. curve, and A. Joannis obtained it by the action of mercury on a soln. of potassammonium in liquid ammonia. There is some uncertainty about the composition of this product.

N. S. Kurnakoff showed that the enneamercuride may be KHg_{10} ; and K. Kraut and O. Popp, W. Kerp and co-workers have reported the preparation of **potassium decamercuride**, KHg_{10} ; J. H. Croockewit by melting together the components; G. P. Grimaldi by melting and cooling an amalgam with 1.77 per cent. of potassium; and A. Guntz and J. Féréé, by compressing the dodecamercuride at 200 kgms. per sq. cm. It melts about 60° . G. P. Grimaldi measured the electrical resistance. E. Maey reported **potassium hendecamercuride**, KHg_{11} , and J. H. Croockewit, **potassium dodecamercuride**, KHg_{12} , by melting together the constituents; by K. Kraut and O. Popp, by the action of potassium hydroxide or carbonate, not acetate or chloride, on 3 per cent. sodium amalgam; by A. Guntz and J. Féréé, by warming the octodecamercuride with potassium; W. Kerp and co-workers, by pressing the tetradecamercuride; and W. Kerp, by cooling for some days at 0° the amalgam prepared electrolytically. The crystals of the alleged dodecamercuride belong to the cubic system; they are stable between 0° and 70° ; and they melt and decompose

at 75°. Various analyses have been made by G. McP. Smith and H. C. Bennett, K. Kraut and O. Popp, W. Kerp and co-workers, etc. M. Berthelot claimed to have shown the existence of *potassium octomercuride*, KHg_8 ; E. Divers, of *potassium heptamercuride*, KHg_7 ; M. Berthelot, and N. S. Kurnakoff, of *potassium hexamercuride*, KHg_6 ; E. Maey, and N. S. Kurnakoff, of *potassium pentamercuride*, KHg_5 . K. Bornemann, and E. Jänecke obtained evidence on the f.p. curve of what was regarded as *potassium hemiennemercuride*, K_2Hg_9 , in six-sided plates melting at 173°, but N. S. Kurnakoff assumed that the penta- or hexa-mercuride is here in question. E. Maey, and M. Berthelot discussed the existence of *potassium tetramercuride*, KHg_4 .

K. Bornemann, N. S. Kurnakoff, E. Maey, and E. Jänecke obtained evidence on the f.p. curve of the existence of crystals of *potassium trimercuride*, KHg_3 , or K_3Hg_9 . The latter gave 204° for the m.p. E. Maey, G. Tammann, K. Bornemann, and E. Jänecke likewise obtained evidence of *potassium dimercuride*, KHg_2 ; and G. Tammann, E. Maey, and E. Jänecke of *potassium monomercuride*, KHg , melting at 178°. E. de Souza prepared a crystalline mass of *potassium hemimercuride*, K_2Hg , by heating potassium amalgam with an excess of mercury to 440°. F. C. Accum, W. Böttger, and G. McP. Smith prepared mixed sodium and potassium amalgam; and E. Jänecke, by using eq. proportions of the constituent elements, obtained *sodium potassium mercuride*, NaKHg_2 , melting at 188°.

N. S. Kurnakoff found the f.p. curve of rubidium amalgam has a maximum at 136.5° corresponding with *rubidium hexamercuride*, RbHg_6 , and there are indications of *rubidium tetramercuride*, RbHg_4 , and *rubidium dimercuride*, RbHg_2 . W. Kerp and co-workers, and G. McP. Smith and H. C. Bennett also studied these amalgams. G. McP. Smith and H. C. Bennett also claimed to have formed silvery cubic crystals of *rubidium dodecamercuride*, KHg_{12} , by centrifuging the amalgam. It melts with decomposition below 0°. The f.p. curve for caesium amalgams has been studied by N. S. Kurnakoff and G. J. Zukowsky, A. Gorboff, C. H. Desch, K. Bornemann, and G. McP. Smith and H. C. Bennett. There is a maximum at 208.2° corresponding with *caesium dimercuride*, CsHg_2 , Fig. 45; one at 163.5° corresponding with *caesium tetramercuride*, CsHg_4 , or CsHg_3 ; and one at 157.7° corresponding with *caesium hexamercuride*, CsHg_6 ; and at about 13° *caesium decamercuride*, CsHg_{10} , is formed; there are also indications of the formation of *caesium hemimercuride*, Cs_2Hg , and *caesium monomercuride*, CsHg . The mercurides of the type MHg_2 , MHg_4 , and MHg_6 thus appear to be common to the four alkali metals $\text{M}=\text{Na}, \text{K}, \text{Rb}, \text{and Cs}$. N. S. Kurnakoff also thinks that similar cadmides are formed— MCD_2 , MCD_4 , and MCD_6 . G. McP. Smith and H. C. Bennett claimed to have made crystals of *caesium dodecamercuride*, CsHg_{12} , by centrifuging the amalgam.

The physical properties of the alkali amalgams.—Lithium amalgam with 0.597 per cent. of lithium was found by W. Ramsay³ to give needle-like crystals which melted in air. W. A. Lampadius found that sodium amalgam with 3.2 per cent. of sodium has a crystalline fracture and can be filed to a powder; and a 2.44 per cent. amalgam is solid. L. Schütz found that amalgams with 3–10 per cent. of sodium are hard brittle solids; and K. Kraut and O. Popp found that the 1.9 per cent. amalgam has needle-like crystals. R. Böttger found a 1.6 per cent. amalgam forms a pasty mass at 21°; likewise also a 1.23 per cent. amalgam; a one per cent. amalgam also has a liquid and a solid portion; while J. L. Gay Lussac and L. J. Thénard found a 0.78 per cent. amalgam is liquid. According to A. Battelli,

FIG. 45.—Freezing-point Curve of Caesium Amalgams.

amalgams with the atomic ratio between Na : Hg = 1 : 495 and 1 : 15 are liquid, those with more sodium are solid. H. Davy found a 3.2 per cent. potassium amalgam is hard and brittle, a 1.4 per cent. amalgam is solid, and a more dil. amalgam is liquid. J. L. Gay Lussac and L. J. Thénard found that amalgams with over 1 per cent. of potassium are solid, and liquid with less than 0.7 per cent. of potassium. R. Böttger found that the amalgam is solid, and one with 0.55 per cent. potassium is friable and partly crystalline, and that with 0.5 per cent. of potassium, the amalgam is viscid. The m.p. curves for the alkali amalgams are indicated in Figs. 41 to 44.

The solid amalgams of the alkali metals are lighter than mercury or dil. liquid amalgams, and therefore float on the surface of these liquids. E. Maey's determinations of the sp. vol. of the alkali amalgams furnish the following values for their **specific gravity**. The results show that the sp. gr. becomes progressively less as the conc. of the alkali metal increases.

Per cent. Li	. 0.0301	0.503	2.166	8.39	11.03	19.58
Sp. gr.	. 13.500	13.135	10.925	6.050	5.030	2.945
Per cent. Na	. 0.103	0.597	2.631	5.08	11.50	39.50
Sp. gr.	. 13.448	12.965	11.701	10.101	6.743	2.420
Per cent. K	. 0.184	0.950	2.82	5.14	12.87	18.61
Sp. gr.	. 13.371	12.908	11.564	9.950	6.406	4.737

Measurements were also made by J. R. Withrow and co-workers, E. S. Shepherd, J. Whiting, W. Kerp, etc. E. Vanstone sought a relation between the mol. vol. of the sodium amalgams and valency. G. McP. Smith measured the speed of **diffusion** and **surface tension** of alkali amalgams. E. Maey found the **coefficient of cubical expansion** of liquid sodium amalgams between 10° and 20° to be $\alpha = 0.000181 + 0.000127w$, where w represents the per cent. of alkali metal; for liquid potassium amalgams, $\alpha = 0.000181 + 0.000065w$; and for lithium amalgams, $\alpha = 0.000181 + 0.000017w$. According to L. Schüz, the **specific heat** of an amalgam with 10 per cent. of sodium between 62.2° and 63.2° is 0.06013—0.05930; between —21.65° and —21.37°, 0.05387 to 0.05396; between —39.91° and —39.43°, 0.05113 to 0.05076; and between —77.37° and —77.04°, 0.05167 to 0.05213. Likewise for a 3 per cent. sodium amalgam, between —20.52° and —20.76°, 0.03788 to 0.03818; and between —79.28° and —79.59°, 0.04050 to 0.04230. G. N. Lewis and C. A. Kraus found the **heat of solution** of one eq. of sodium in a large quantity of 0.206 per cent. sodium amalgam to be 19.79 Cals. M. Berthelot gave 16.2 Cals. for the **heat of formation** of NaHg₂ from liquid mercury; 11.4 Cals. for NaHg; 13 Cals. for Na₃Hg; H. von Wartenberg gave 13,000 cal. \pm 10 per cent. M. Berthelot found for the heat of formation of KHg, 12.1 Cals.; for KHg₂, 19.8 Cals.; and for KHg₃, 29.1 Cals. M. Berthelot calculated from the heat developed by the action of hydrochloric acid, the heat of combination per 2 eq. of potassium for amalgams:

K per cent.	. 0.337	0.65	1.34	1.85	2.00	3.40	8.01	11.85
Cals.	. 26.2	30.2	33.7	34.2	34.8	29.7	20.6	15.3
	Liquid		Mush	Solid				

Similarly, for sodium amalgams:

Na per cent.	. 0.45	0.85	1.88	2.47	4.80	5.45	10.0
Cals.	. 18.8	19.8	21.1	21.1	18.0	17.8	10.3
	Liquid		Mush	Solid			

The **vapour pressures** of the metal-amalgams have been measured by W. Ramsay,⁴ and the conclusion drawn that the metals are monatomic when dissolved in mercury. H. von Wartenberg failed to get satisfactory measurements of the vap. press. of the compound Na₃Hg. He assumed that a compound exists

in the state of vapour at about 500° , but O. Neumann's vap. press. observations do not support this hypothesis. C. T. Heycock and F. H. Neville have measured the **freezing point** of amalgams and have drawn similar conclusions. G. Tammann likewise inferred that the metals are dissolved as simple monatomic mols. A. Larsen inferred that the degree of ionization of the dissolved metal increases with decreasing conc. and rising temp. G. Meyer showed that the e.m.f. E of cells with amalgam electrodes containing a different proportion C_1 and C_2 of metal, and a salt soln. used as electrolyte, is given by $nE = RT \log (C_1/C_2)$, where R is the gas constant, T the absolute temp., and n the number of unit charges carried by a mol. of the metal. If the metal is monatomic, n represents the valency of the metal; and if the metal has a polyatomic mol., then dividing n by the valency, there remains n' the number of atoms in the mol. The value of n/n' was found by A. Schöller, T. W. Richards and G. N. Lewis, and H. Fay and E. North to be equal to unity with a number of amalgams. F. Haber showed that the conclusion is not justified unless it can be shown that the dissolved metals are not present as compounds MHg_n . K. Bornemann also showed that these deductions apply only with solutes which have no inclination to form compounds with the solvent. G. McP. Smith also showed that the f.p., and the vap. press. methods prove only that the solute is present either in single atoms or as mols. MHg_n . According to V. Merz and W. Weith, L. Schütz, and G. McP. Smith, the general results show that *in all probability amalgams are soln. of compounds of the dissolved metal with certain definite proportions of the solvent mercury in an excess of mercury*. E. Beckmann and O. Liesche found the effect of the alkali metals on the b.p. of mercury corresponded with the formation of $NaHg_{5 \text{ or } 6}$, and of $KHg_{12, 13, \text{ or } 14}$ at these temp.

L. Arons⁵ found that when sodium amalgam is used as electrode for the **amalgam arc-lamp** the electrode tension is smaller than with mercury, and the sodium lines are strongest in the spectrum at the cathode. Potassium amalgam behaves similarly, but the spectrum rarely shows potassium lines. The **photo-electric effect** with potassium amalgams has been studied by R. Pohl and P. Pringsheim. F. H. Newman studied the spark spectra of the alkali amalgams.

The **electric conductivity** of sodium amalgam shows no discontinuity between 107° and 133° , but is rapidly lowered by alloying sodium with the mercury; there is a break in the curve at the eutectic point, and another when 22.1 atomic per cent. of mercury is present. This does not coincide with the thermal diagram, where the curve passes through a flat minimum. According to R. C. Rogers,⁶ there is a sharp bend in the curve showing the relation between the percentage change of electrical resistance and the composition at the eutectic point and 5.9 atomic per cent. of sodium, but the curve is smooth if the specific resistance be plotted against the atomic composition. K. Bornemann and G. von Rauschenplat measured the sp. resistance R and the sp. conductivity of lithium, and sodium amalgams of different conc. and a different temp. and found

		50°	100°	150°	200°	250°	300°
0.003 per cent. Li	$\left\{ \begin{array}{l} R \\ \lambda \end{array} \right.$	0.9882	1.0380	1.0921	1.1540	1.2218	1.2954×10^4
		1.0117	0.9634	0.9157	0.8665	0.8185	0.7720×10^{-4}
0.043 per cent. Li	$\left\{ \begin{array}{l} R \\ \lambda \end{array} \right.$	0.9750	1.0150	1.0700	1.1270	1.1920	1.2590×10^4
		1.0257	0.9852	0.9346	0.8873	0.8389	0.7943×10^{-4}

they also computed the temp. coeff. of the resistance. Similarly for 0.11 per cent. sodium amalgam:

R	.	.	.	0.9976	1.0274	1.1020	1.1656	1.2360	1.3142×10^4
λ	.	.	.	1.0024	0.9733	0.9074	0.8579	0.8091	0.7609×10^{-4}

G. P. Grimaldi, P. Müller, and A. Battelli measured the electrical conductivity of sodium and potassium amalgams at different conc. and temp.

A. Coehn and A. Lotz⁷ found that potassium and sodium amalgams in vacuo are negatively charged with respect to glass. According to A. Oberbeck and J. Edler,

the **electromotive force** of the amalgams towards mercury is in general equal to that of the metals themselves. G. McP. Smith found that the electrochemical series of the alkali amalgams in an eq. soln. of a mercury salt is : +Li, K, Rb, Cs, Na-; and he measured the e.m.f. of different alkali amalgams against potassium amalgam. M. Reuter measured the potential of potassium amalgam against $\text{Hg}(\text{Hg}_2\text{O})$, N.KOH in a methyl alcohol soln. of lithium chloride. F. Haber and M. Sack, and W. Kettenbeil made analogous observations with sodium amalgams. G. N. Lewis and C. A. Kraus measured the e.m.f. of sodium amalgams and sodium. E. Branly measured the e.m.f. of sodium amalgam against mercurous sulphate and carbon. T. W. Richards and J. B. Conant measured the e.m.f. of conc. cells of sodium amalgams at 15° and 25° , and the deviations from the simple concentration law were greater than with any other amalgam yet studied. The heats of transfer of sodium from one amalgam to another were calculated. F. Glazer, measured the e.m.f. of the cell $\text{K}_{\text{amalgam}} | \text{KCl} | \text{Cl}$; J. Regnaud, of potassium amalgam in a soln. of potassium iodide with some iodine, bromine, or chloride against carbon in a soln. of potassium iodide; E. Beetz, of $\text{K}_{\text{amalgam}} | \text{KOH} | \text{KMnO}_4 | \text{MnO}_2$; C. Hockin and H. A. Taylor, the e.m.f. of potassium or sodium amalgam against amalgamated zinc in a conc. soln. of zinc sulphate, and under molten paraffin; C. Wheatstone, of $\text{K}_{\text{amalgam}} | \text{ZnSO}_4$ soln. against CuSO_4 soln. and Cu or dil. H_2SO_4 and PbO_2 , or dil. H_2SO_4 and MnO_2 ; M. le Blanc, of $\text{K}_{\text{amalgam}}$ in a *N*-soln. of sodium chloride against zinc amalgam, and similarly also with sodium amalgam in *N*- NaCl . Other observations were made by G. Meyer, H. P. Cady, A. Schöller, etc. T. W. Richards and K. N. G. Thomas measured the e.m.f. of lithium amalgam against pyridine soln. of lithium chloride; and G. N. Lewis and F. G. Keyes, in propylamine sat. with lithium iodide, as well as against a normal calomel electrode. B. S. Neuhausen measured the e.m.f. of cells made with sodium amalgam, soln. of sodium chloride, and the calomel electrode. T. W. Richards and G. S. Forbes did not find an indifferent electrolyte for cells with sodium-amalgam electrodes. G. N. Lewis, E. Q. Adams, and E. H. Lanman found the transport of the metal is not related to an increase or decrease in the resistance of the mercury produced by the dissolution of the metal. G. Mayr stated that the solute metal during electrolysis is transported towards the anode, and that with respect to the transport, there is no appreciable distinction (i) between metals, like thallium, which form compounds with the mercury, and those, like zinc, which dissolve in the mercury; and between metals, like sodium and potassium, which increase the resistance of the mercury, and those, like zinc, which diminish the resistance. S. B. Frank and J. R. Withrow studied the **electro-endosmosis** of the alkali metal amalgams. F. Skaupy considered the effect of the hydrargyration of the mercury ions on the transport number of liquid amalgams.

Some chemical properties of the alkali amalgams.—H. Davy⁸ found that sodium and potassium amalgams readily change when exposed to the **air**; M. Berthelot showed that a superficial film of alkali hydroxide or carbonate is formed; and L. Schüz found a 9.58 per cent. potassium amalgam oxidizes in a few minutes. G. McP. Smith found lithium amalgam is less stable in air than either sodium or potassium amalgam. G. S. Johnson found that liquid sodium or potassium amalgam retains an untarnished lustre in dry **oxygen** at ordinary temp. and at press. ranging from 0.05 mm. to a little over 760 mm. The amalgam kindled when heated below redness in dry oxygen and burned with explosive violence. G. McP. Smith said that with potassium amalgam, a dark film of potassium suboxide mixed with mercury is first formed, and he found that while the purified amalgam reacts slowly with water, that which is partially oxidized reacts turbulently. H. Davy found that **water** slowly decomposes alkali amalgam, furnishing hydrogen, mercury, and potassium hydroxide; dil. acids act similarly, producing the corresponding alkali sat. N. S. Kurnakoff and G. J. Zukowsky found that the last three of **cæsium** are retained very tenaciously by **cæsium** amalgam in the presence of water; and G. McP. Smith observed that lithium amalgam is decomposed by

water more vigorously than potassium or sodium amalgam. E. Müller and A. Riedel determined the rate of decomposition of water by 0.2 per cent. sodium amalgam in the presence of metallic and other substances. The amalgam (80 grms.) was rapidly stirred with 50 c.c. of water and a piece of the metal in question, and the hydrogen collected and measured. The experiments were carried out with ferro-molybdenum, cast iron, wrought iron, iron carbide, silicon, ferro-silicon, ferro-vanadium, ferro-tungsten, chromium, platinum, palladium, iridium, nickel, cobalt, manganese, tantalum, graphite, and ferric oxide. It is shown that the iron alloys of molybdenum, vanadium, tungsten, and chromium have a very strong catalytic action on the process. This action depends on the increase in the surface of the amalgam due to the soln., and subsequent separation of the metals. There is a possible application of this action to the manufacture of sodium hydroxide by the mercury electrode process. O. W. Richardson measured the emission of electrons when potassium-sodium alloys are dropped through water vapour at a low press. K. Kraut and O. Popp obtained KHg_{12} by the action of a 3 per cent. sodium amalgam on an aq. soln. of **potassium hydroxide, or carbonate**. F. Haber and M. Sack observed that when an amalgam with more than 15 per cent. of sodium is dipped in water or a soln. of **sodium hydroxide**, it first becomes spongy, and then furnishes hydrogen, while amalgams poor in sodium give off hydrogen from the beginning. W. Kerp added that the decomposition of sodium amalgam by water or a soln. of a sodium salt progresses very slowly, with a soln. of commercial sodium hydroxide turbulently, and with a soln. of purified sodium hydroxide slowly. G. Fernekes found that with N - or $\frac{1}{10}N$ -soln. of **sodium aluminate, hydrocarbonate, hydrophosphate, sulphite**, or the ordinary hydroxide, the action accompanied by the evolution of hydrogen is more violent than with water; and less violent with soln. of **sodium chloride, bromide, iodide, sulphate, borate, pyrophosphate, acetate**, or the purified hydroxide. J. Schumann found that a one per cent. sodium amalgam decomposes most of the **metal chlorides** and forms with them the corresponding amalgam, and likewise also by triturating the alkali amalgam with the powdered **metal**. According to N. Bunge, **mercuric or auric chloride** and the **silver halides** are easily reduced by sodium amalgam; silver chloride is not reduced under petroleum; an aq. soln. of **ferric chloride** is reduced partly to ferrous chloride, partly to the metal, and if sufficient amalgam is present, iron-amalgam is formed; an ethereal soln. of ferric chloride is changed but slowly; and a dil. hydrochloric acid soln. of **chromic chloride** furnishes a green liquid and chromium amalgam. O. W. Richardson studied the emission of electrons when potassium-sodium alloys are dropped through **carbonyl chloride, chlorine, and hydrogen chloride** at a low press.

R. Böttger, H. G. Byers, and G. McP. Smith found that sodium amalgam reacts with **salts of the alkaline earths or the heavy metals** in the presence of a little water, forming the corresponding amalgams. Similar results were obtained with potassium salts, and generally, potassium amalgam reacts more strongly than does sodium amalgam with soln. of **sodium or potassium salts**. G. McP. Smith showed that the action of various salt soln. on the alkali amalgams results in the partial displacement of the alkali in the amalgam by the alkali in the salt soln., and the same equilibrium is obtained by the action of eq. soln. of **potassium, sodium, rubidium, or caesium chloride** on potassium, sodium, or lithium amalgam. For the reaction $\text{NaHg}_n + (m-n)\text{Hg} + \text{M}^+ = \text{MHg}_n + \text{Na}^+$, the equilibrium constant is 0.31 when M represents K; 0.37, when $\text{M} = \text{Rb}$; and 0.48, when $\text{M} = \text{Cs}$. The stability of the alkali amalgams increases in the order of their chemical activity in air, water, or in aq. soln. of the chlorides LiHg_n , KHg_n , RbHg_n , CsHg_n , and NaHg_n . S. A. Braley and co-workers, and G. McP. Smith and co-workers also studied the action of mixed alkali salt soln. H. Davy found that moist **ammonium salts** with potassium amalgam give a potassium salt and ammonium amalgam. According to J. Proude and W. H. Wood, sodium amalgam does not give ammonium amalgam with aq. **ammonia**, with ammoniacal soln. of **sodium hydrophosphate**; calcium

chloride; magnesium sulphate; molten ammonium sulphate, nitrate, or acetate; or with ethyl or methyl alcoholic soln. of ammonium chloride, oxalate, acetate, benzoate, tartrate, or succinate; but it does so with soln. of phenol or pyrogallol in ammonia.

M. Rosenfeld found that when a stream of air is passed over molten potassium amalgam, a grey ash remains; this becomes brownish-red when heated to a higher temp. H. Davy found that the solid amalgam loses its mercury at a red heat, and V. Merz and W. Weith, that potassium amalgam is more rapidly decomposed by heat than is sodium amalgam. When the alkali amalgam is distilled, H. Davy found it to be very difficult to obtain a complete separation.

D. Tommasi found that **potassium chlorate** is not reduced by sodium amalgam; E. Fromm and O. Gaupp, that **sulphuryl chloride** is not reduced in petroleum ether soln., but is vigorously reduced in ethereal soln.; T. Curtius and A. Darapsky, that **azoimide** is not reduced in alkaline soln.; A. R. Hantzsch and L. Kaufmann, that **sodium nitrite** is reduced to hyponitrite; E. Frémy, that **arsenious oxide** or an arsenite is reduced to an unstable product which reduces cold potassium permanganate, and salts of copper, silver, gold, or mercury; and E. A. G. Street, that **chromic acid** is energetically reduced. G. Fernekes found that aq. soln. of **hydrocarbons** react more vigorously with sodium or potassium amalgam than with water, in spite of their low solubility in water; **amide** soln. act as rapidly as aq. soln.; **toluidine** and **xylydine** more slowly than in water. Soln. in **alcohols**, **ketones**, and different kinds of **sugar** were also investigated. E. Fischer, W. Wislicenus, A. von Baeyer, A. H. Salway, etc., have studied the reducing action of sodium amalgam on **organic compounds**. B. Fetkenheuer found **carbon tetrachloride** is quantitatively decomposed by warm sodium amalgam: $4\text{Na} + \text{CCl}_4 = 4\text{NaCl} + \text{C}$. E. Vanstone found that sodium amalgam with a high sodium content is more satisfactory than sodium alone as a reducing agent in organic chemistry, and he recommended an amalgam liquid at 21.4° which contains 85° at. per cent. of sodium.

According to H. Davy, potassium and sodium amalgams readily amalgamate **iron** and **platinum**. Sodium amalgam was found by A. C. Christomanos to convert **zinc**, **copper**, and **platinum** into their amalgams, but not so readily **magnesium**. E. Ramann found **ferric oxide** is readily attacked by sodium amalgam. W. Crookes,⁹ H. Wurtz, J. Nicklès, E. P. H. Vaughan, J. B. Thomson, E. Silliman, and L. P. Cailletet have discussed the use of sodium amalgam in the extraction of gold.

§ 40. Amalgams of Copper, Silver, and Gold

W. J. Humphreys¹ found that copper dissolves very sparingly in mercury, at room temp. H. Iggena found the percentage solubility to be 0.16; T. W. Richards and R. N. G. Thomas, 0.0024 per cent.; and A. Gouy, 0.001 per cent. E. N. Horsford said that copper is not permeable to mercury, but J. Nicklès, and A. Knop found it to be slightly permeable and the metal to become brittle, but C. Diezel found that some varieties of copper do not become friable. A piece of copper foil in a soln. of mercuric nitrate is gradually penetrated by the precipitated mercury, and thus becomes brittle; R. Lacau used an acidified soln. of mercuric nitrate; W. J. Humphreys found that copper diffuses rapidly in mercury. N. A. Puschin said that the chemical nature of copper is not altered when diluted with mercury. J. P. Joule said that the amalgam prepared by electrolysis, and by dissolving copper in mercury, has the composition of copper mercuride, CuHg; but the evidence for the individuality of this product is meagre. J. Schumann said the sp. gr. is 12.655, while that calculated on the assumption that the product is a mixture, is 12.00.

The preparation of copper amalgam.—R. Boyle, and W. Lewis obtained copper amalgam by triturating mercury with verdigris and common salt; the former used a little vinegar, and purified the product by washing. J. Schumann

failed to verify these observations. J. P. Joule prepared an amalgam approximating to CuHg , by dissolving copper in mercury, and removing the excess of the latter by strong press. W. Ramsay, and D. Reichinstein and A. Bürger stated that copper readily amalgamates with mercury, if the surface of the copper be cleaned with dil. sulphuric acid, washed with distilled water, and dried with filter paper; a little of dry mercury is then rubbed over the surface of the copper and the excess of mercury removed. E. and A. C. Becquerel allowed a strip of copper to stand in contact with mercurous chloride immersed in distilled water. J. J. Berzelius, R. B. Boulton, M. Gersheim, C. R. König, M. Pettenkofer, etc., triturated copper dust reduced from the oxide by carbon monoxide or precipitated from a soln. of the sulphate by zinc or iron, with mercury and a few drops of mercurous nitrate, or with a mush of mercuric sulphate and water at 60° – 70° . E. W. Jungner used a modification of this process. J. Schumann precipitated the copper from the cupric sulphate soln. while in contact with mercury. A. C. Christomanos brought the copper sheet in contact with ammonium amalgam; C. Klauer, and J. Schumann used one per cent. sodium amalgam in a soln. of cupric sulphate; R. Böttger used a conc. soln. of cupric sulphate and ammonium chloride; and A. A. Damour, zinc amalgam in an ammoniacal soln. of cupric sulphate. W. R. Grove, J. P. Joule, H. Iggena, J. Schumann, and A. Guntz and M. de Grieff, prepared copper amalgam by the electrolysis of a soln. of cupric sulphate with a mercury cathode. C. Paal and H. Steyer prepared **colloidal copper amalgam** by shaking copper hydrosol with mercury, or by mixing copper and mercury hydrosols.

The properties of copper amalgam.—The colour of copper amalgam varies from silver-white to a golden-yellow, and to a light red. J. P. Joule, H. Iggena, and J. Schumann obtained **crystals**, which A. C. Becquerel regarded as rhombic prisms with pyramidal ends. P. I. Bachmetjeff found that a contraction in volume attends the formation of copper amalgam. J. Schumann found that a 13·4 per cent. amalgam has a **specific gravity** of 12·653 when liquid, and, after solidification, 12·90; while an amalgam approximating to HgCu has a sp. gr. 12·655—the values calculated from the mixture rule are respectively 12·37 and 12·00. J. P. Joule found for the sp. gr. of copper amalgams:

Hg (per cent.) . . .	81·63	80·20	80·00	78·36	76·13	77·52	74·52	71·63
Sp. gr.	13·32	13·26	13·185	13·17	13·51	13·76	13·01	12·99

G. Meyer measured the **surface tension** of a 0·00505 per cent. copper amalgam against salt soln. E. von Schweidler measured the coeff. of **viscosity** of a 0·5 per cent. copper amalgam and found the value 0·01620 with a temp. coeff. $\eta=1-0·00302\theta+0·0000025\theta^2$. According to A. Guntz and M. de Grieff, amalgams containing 14 per cent. of copper, Hg_3Cu_2 , up to 24·10 per cent. of copper, HgCu , may be prepared by a **pressure** of 6250 kgrms. per sq. cm., and by the same press. with boiling mercury, amalgams with 45 to 97 per cent. of copper have been made. J. Schumann found the **cubical expansion** between 17° and 155° is 3·1 per cent. for a 13·4 per cent. amalgam, and 6·6 per cent. for the amalgam approximating to CuHg . According to A. Guntz and M. de Grieff, the **melting point** of the amalgam approximating HgCu is approximately 135° . E. de Souza said that the **action of heat** on copper amalgam furnishes HgCu_{16} in a bath of sulphur vapour, HgCu_{14} , in the vapour of mercury and in the vapour of diphenylamine; but V. Merz and W. Weith found that after 8 hrs. in a sulphur vapour-bath, or 24 hrs. in a mercury vapour-bath, the product is virtually pure copper, and only 0·66 per cent. of mercury remained in an amalgam heated 22 hrs. in a diphenylamine-bath. T. W. Richards and S. K. Singer found that all the mercury can be volatilized over 350° in a stream of hydrogen, and that a trace of copper is volatilized at a higher temp. A. Coehn and A. Lotz found copper amalgam in vacuo is positively charged when in contact with glass. A. Battelli, and A. P. Schleicher measured the **electrical resistance**; G. Meyer obtained evidence of the ionization of both copper and mercury in the dil. amalgam. G. Meyer measured the **electromotive force** in

soln. of *sodium hydroxide, potassium cyanide, sulphuric acid, hydrochloric acid, potassium iodide, sodium carbonate, magnesium sulphate, and lead acetate*; V. Rothmund, with $N\text{-H}_2\text{SO}_4$, and $\frac{1}{200}N\text{-CuSO}_4$; N. A. Puschin, $\text{Cu} \mid N\text{-CuSO}_4 \cdot 5\text{H}_2\text{O} \mid \text{CuHg}_n$; C. Hockin and H. A. Taylor, $\text{CuHg}_n \mid \text{dil. H}_2\text{SO}_4 \mid \text{ZnHg}_n$; and J. F. Spencer, with $N\text{-soln. of cupric salts}$. E. Cohen, F. D. Chattaway, and W. Tombrock found the e.m.f. of cells with copper amalgam is independent of the conc. between 1 and 16 per cent. of copper; C. R. A. Wright, D. Reichinstein and A. Bürger, and G. Gore have also studied this question. J. Roszkowsky measured the hydrogen polarization with copper amalgam as cathode. L. W. Ohlm investigated the e.m.f. of cells with copper amalgam in cupric sulphate soln. against mercury and mercuric sulphate. R. Lacau found that the surface of amalgamated copper retains its lustre in acidic soln., but in air or water, it soon turns greenish-grey; and A. Vogel found that the surface of copper amalgamated not too thickly loses its metallic film after 12 hrs.' exposure to air. M. Pettenkofer found that hot water, dil. acids or alkalies, alcohol, or ether do not attack copper amalgam. According to M. Pettenkofer, and W. F. A. Thomæ, copper amalgams have been used in making blocks for printing diagrams, and as dental cement, and in the amalgamation process for gold. J. Alemany has discussed the use of amalgamated copper cathode in place of the mercury cathode for analytical work.

Silver amalgams.—The power possessed by mercury of "licking up" gold and silver must have been known from early times. Pliny, in his *Historia naturalis*, refers to the amalgamation of gold. According to A. Cronstedt,² *silver amalgam*—or simply, *amalgam*, or *argental*—was found as a mineral at Sala (Sweden) about 1660. The native amalgam has since then been reported from many other localities, and in some cases given special names—*arguerite*, from Arqueros in Chile; *bordosite*, from Bordes in Chile; and *kongsbergite*, from Kongsberg in Norway. The reported analyses range from Ag : Hg = 18.64 : 81.36 to 95.8 : 3.6 per cent.

According to J. F. Daniell,³ when a silver rod is immersed in mercury at ordinary temp., a little is dissolved in the course of 24 hrs., but the rod remains malleable—even in 6 weeks, very little silver is dissolved by the mercury; but if the mercury be gradually heated to its b.p., and then slowly cooled, soft acicular crystals of an amalgam are deposited on the silver rod near the surface of the mercury. W. Haidinger reported that the two metals unite very slowly and that the silver becomes crystalline and brittle, and not infrequently covered with large crystals. Such crystals of amalgam were found by J. B. A. Dumas, G. Küstel, and C. A. Kennigott, in the mercury wells where amalgamation processes are used. A. Ogg found a little silver dissolved in mercury at room temp. W. J. Humphreys said that 0.05 per cent. is dissolved at 27°, and more at a higher temp., as observed by J. B. L. Romé de l'Isle. A. Gouy also measured the solubility of silver in mercury, and found it rises rapidly with temp. W. Reinders dissolved about 2 per cent. of silver in mercury; and A. Feodoroff, about 6 per cent. in an open vessel. E. Maey showed that the amalgams cannot be prepared in any desired proportion by melting the constituents together, because the m.p. of silver is so much higher than that of mercury, and the solid amalgam is but sparingly soluble in mercury; he obtained an amalgam by dissolving silver in heated mercury, poured off the liquid amalgam, and after cooling, removed the liquid from the solid amalgam by press. W. J. Humphreys found the rate of diffusion of silver in mercury to be very rapid—20 mm. per minute.

K. A. Winkler found that mercury has scarcely any action on silver oxide or silver silicate at ordinary temp., and that silver amalgam and mercuric sulphide are formed when mercury and silver sulphide are triturated together for a long time; silver chloride also when triturated with mercury and water behaves similarly, and the presence of a little sodium chloride or sulphate accelerates the reaction, and the reaction is quite rapid if some powdered iron be present; copper acts in the same way but less vigorously; silver sulphate and mercury similarly form mercurous sulphate and silver amalgam. J. W. Mallet and R. Segura found that precipitated silver

sulphide or native argentite is reduced to silver amalgam and mercuric sulphide when triturated with mercury and water; the amalgamation proceeds faster with a small than with a large proportion of water. J. H. Croockewit, J. Schumann, J. P. Joule, L. Arons, and S. Lindeek found that a not too conc. soln. of silver nitrate is reduced by mercury, and that the precipitated silver unites with a portion of the mercury, forming a crystalline amalgam in the form which J. B. L. Romé de l'Isle said is *très-connu sous le nom d'arbre de Diane*—silver-tree, or *arbor dianæ*. If the proportion of mercury be too large, the product is liquid, not crystalline, and to form the tree mercury amalgamated with one-eighth of silver was recommended by M. H. Klaproth, G. Küstel, and J. J. Berzelius, but J. L. Proust found mercury alone acts as well. A little free acid accelerates the reaction. A. Ogg studied the equilibrium conditions between mercury and soln. of silver nitrate, and obtained results in accord with $2\text{Hg} + 2\text{Ag}^+ \rightleftharpoons 2\text{Ag} + \text{Hg}^+ - \text{Hg}^+$, and not $\text{Hg} + \text{Ag}^+ \rightleftharpoons \text{Hg}^+ + \text{Ag}$. J. B. Vitalis, and F. Fouqué and A. M. Lévy used a soln. containing both silver and mercury nitrates. D. Dehne analyzed a silver-tree with 81.36 per cent. of silver. F. L. Hünfeld found that if mercury be left for a long time at the bottom of a dil. soln. of silver nitrate, the silver-tree first formed is dissolved by the underlying liquid amalgam, and after a time, long four-sided lustrous prisms containing 68.3 per cent. of silver were formed. R. Böttger also prepared silver amalgam by the action of sodium amalgam on a soln. of a silver salt.

G. Campani found that silver, particularly if finely divided, precipitates mercury and forms an amalgam when added to a soln. of mercuric chloride, or of potassium mercuric iodide, at ordinary temp. H. C. Jones claimed to have made silver amalgams of definite composition by preparing a double salt of a definite mixture of salts of the two metals with the subsequent reduction in the cold. When mercuric chloride, for example, acts on either silver or mercury, or an amalgam of the two metals, each atom of either metal combines with a mol. of mercuric chloride. The chloride is then reduced by means of a soln. of ferrous oxalate mixed with an excess of potassium oxalate to keep the iron salts in soln. A soln. of sodium sulphite may also be used as the reducing agent. A. C. Becquerel obtained crystals of silver amalgam by allowing soln. of silver and mercurous nitrates to be separated by a cracked glass tube. W. Reinders obtained silver amalgam by shaking a mixed soln. of mercurous and silver nitrates with mercury. A. C. Becquerel also allowed a mixture of mercurous and silver chlorides to stand under water with a strip of amalgamated copper for some days. J. P. Joule, J. Schumann, and C. Luckow made silver amalgam by the electrolysis soln. of silver salts with a mercury cathode.

Over a dozen chemical compounds have been reported with formulæ based upon analyses, but for most of them there is very little evidence which would justify their being recognized as chemical individuals. For example, the native mineral *arguerite* has been given the formula HgAg_{12} , based upon the analyses of P. Berthier, and I. Domeyko; and the formula Hg_3Ag_2 based on the analyses of J. G. Schreiber, V. Cordier, J. C. H. Heyer, A. Lacroix, etc., has been assigned to native amalgam. Analyses of a native amalgam from Sala by H. Sjögren corresponded with Hg_6Ag_5 —the sp. gr. was 11.56, *vide supra*, the occurrence of silver amalgam. J. H. Croockewit obtained products with compositions corresponding with Hg_4Ag_2 , Hg_8Ag_5 , Hg_3Ag_2 , and HgAg ; H. C. Jones, with Hg_{31}Ag , Hg_{15}Ag , Hg_{11}Ag , Hg_7Ag , Hg_5Ag , Hg_3Ag , Hg_2Ag , and HgAg ; and F. T. Littleton, with Hg_4Ag , which he said has a heat of formation of 3432 cals., and a sp. ht. of 0.029 when the value calculated from the mixture law is 0.0359. The latter also said that the heat of formation of Hg_2Ag from silver foil is 1.53 Cals., and from silver crystals -0.40 Cal. F. L. Hünfeld claimed to have made a compound Ag_4Hg by the action of mercury on a soln. of silver nitrate until the silver-tree first formed has dissolved, and the liquid amalgam has crystallized.

According to E. Maey, the change in the sp. vol. with the conc. of silver amalgam gives a curve which has a break near the value calculated for HgAg , while A. Ogg believes that the composition is better represented by Hg_4Ag_3 . The curve showing the relation between the composition of the amalgam and the vapour pressure shows

the existence of **silver tetratritamercuride**, Hg_4Ag_3 , and HgAg ; and, according to A. Ogg, K. Bornemann, and R. A. Joyner, in an evacuated vessel, the equilibrium between silver and silver saturated with mercury corresponds with Hg_4Ag_3 . W. Reinders obtained large needle-like crystals of Hg_4Ag_3 by shaking mixed soln. of silver and mercurous nitrates in which $\text{AgNO}_3 = 0.57$ to 0.61 ($\text{AgNO}_3 + \text{HgNO}_3$) at 25° for 12 to 20 days. According to A. Ogg, the heat of formation is 7336 cal. per mol.

M. H. Klaproth's analyses of a native amalgam from Moschellandsberg corresponded with HgAg . A. Feodoroff's cooling curves of silver amalgams showed that those with a composition, **silver mercuride**, AgHg , are probably eutectic mixtures. W. Reinders believed that in all probability HgAg does not represent a true compound, while K. Bornemann thought it did. W. Ramsay said that amalgams have this composition after heating to dark redness. J. H. Croockewit claimed to have made an amalgam of this composition by reducing a moderately conc. soln. of silver nitrate with mercury, and H. C. Jones, by the action of silver, or silver-amalgam on a soln. of mercuric chloride. The latter said the sp. gr. is 12.8099 at $20^\circ/20$.

According to W. Reinders, the products Hg_4Ag_3 and **silver ditritamercuride**, Hg_2Ag_3 , separate from a mixture of mercury, and soln. of mercurous nitrate and an excess of silver nitrate, in the proportions $\text{AgNO}_3 = 0.87$ to 1.00 ($\text{AgNO}_3 + \text{HgNO}_3$) for 5.30 days at 25° ; or by shaking finely divided silver for 7–19 days with an excess of a soln. of mercurous nitrate. The crystals of the latter have a reddish tinge; those of the former a bluish tinge. The product also appears as a pale grey powder. R. Müller and R. Hönig made metallic needles of **silver trihemimercuride**, Ag_2Hg_3 , by keeping a drop of mercury in contact with a soln. of silver nitrate and cuprous iodide in dry pyridine. W. Reinders also claimed to have obtained evidence of the formation of a compound **silver tritamercuride**, Ag_3Hg .

According to E. Maey, silver amalgams with 0.13 per cent. of silver are liquid at 17.5° ; one with 10 per cent. of silver was a mush of liquid crystals; and amalgams with more than this amount of silver are solid. According to J. P. Joule, the sp. gr. of some amalgams are:

Silver	.	.	34.5	51.6	53.5	60.9	74.6	72.3 per cent.
Sp. gr.	.	.	14.68	12.49	13.25	12.34	12.54	11.42

According to E. Maey, the sp. gr. of amalgams with up to 29.5 per cent. of silver is almost the same as that of mercury, and the sp. vol. is nearly 0.07380; and with amalgams containing from 9.751 to 37.0 per cent. of silver, the sp. gr. falls from 13.197 to 9.751, and the sp. vol. v is given by $v = 0.0577 + 0.000477w$, where w denotes the per cent. of silver. Amalgams with 77.5 per cent. of silver were obtained by compression, and more mercury can be removed by compressing the warm amalgam—at 100° , an amalgam with 70 per cent. of mercury was formed, and at higher temp., one with 61 per cent. of mercury was produced. Amalgams with still less mercury were obtained by evaporating off the mercury. A. Ogg found that the vap. press. of amalgams containing an excess of mercury is very nearly equal to that of pure mercury, but falls very considerably when the composition approaches Hg_4Ag_3 , and the amalgam is in equilibrium with mercury. W. Ramsay found the vap. press. of an amalgam was lowered 22.8 mm. by the dissolution of 3.22 grm.-atoms of silver in 100 of mercury, and if the silver were atomic, this would correspond with an at. wt. 112.4. E. D. Eastman and J. H. Hildebrand found silver to be very sparingly soluble in mercury at 318° , and an amalgam with 1.27 per cent. of silver has a normal vap. press. in accord with Raoult's law. E. Beckmann and O. Liesche applied the b.p. method of determining the mol. wt. of silver in mercury and the results agree with the view that silver is monatomic. A. Matthiessen and C. Vogt, and N. Parravano and P. Jovanovich, have measured the electrical resistance of silver amalgams; while C. L. Weber found the sp. resistance R , referred to mercury at 18° , to be:

0.25 per cent. Ag			0.5 per cent. Ag.			1.0 per cent. Ag.					
R	.	.	17.2°	37.8°	39.8°	17.2°	18°	42.9°	16.1°	18.0°	43.3°
R	.	.	0.9948	1.0188	1.0276	1.0009	0.9984	1.0245	0.9811	0.9930	1.0105

A. Battelli found the differences between the observed and calculated sp. resistances are negative and increase with increasing proportions of silver, and are positive with $\text{Hg} : \text{Ag} = 400 : 1$; with higher proportions of silver the resistance becomes negative. A. R. Calvo found that for very dil. amalgams with up to 0.06 per cent. of silver, between 0° and 20° , the electrical resistance is a linear function of the conc., and at higher temp. the resistance then furnishes a curve concave to the conc. axis. W. Reinders found that liquid amalgams containing 0.076 per cent. Ag coexist with soln. in which the silver nitrate is 0.25 per cent. of the total salts; the compound Ag_3Hg_4 coexists with soln. containing from 2.5 to 18 per cent. of silver nitrate; the compound Ag_3Hg_2 coexists with soln. containing from 18 to 40 per cent. of silver nitrate; the compound Ag_3Hg coexists with soln. containing from 40 to 100 (nearly) per cent. of silver nitrate; solid soln. of mercury in silver coexist with soln. containing practically nothing but silver nitrate. The potential difference metal/soln. changes with composition in a manner which is in harmony with the equilibria just described. A. Ögg found the polarization e.m.f. is very nearly equal for soln. of silver and mercurous nitrates, but is lower for mixtures than for either soln. alone; and silver amalgam is a "nobler" metal than either of its constituents with respect to soln. of mercurous and silver nitrates. S. Lindeck, and G. Gore measured the e.m.f. of silver amalgams, and C. Hockin and H. A. Taylor of amalgamated silver against amalgamated zinc in dil. sulphuric acid. R. Müller and R. Hönig found the e.m.f. of the cell $\text{Ag} \mid 0.1N\text{-AgNO}_3 \mid \text{pyridine} \mid \text{Hg}$ is 0.038 volt; but if the pyridine is sat. with cuprous iodide, the e.m.f. is 0.37 volt. L. Arons found that the voltage for the arc lamp is higher with silver amalgam than with mercury alone—the spectrum of silver appears only in the light at the cathode. A. Coehn and A. Lotz found that silver amalgam is positively charged with respect to glass in vacuo.

When silver amalgam is heated, the mercury volatilizes, but, according to J. L. Gay Lussac, some mercury is retained even at the m.p. of silver. E. de Souza found that in a sulphur vapour-bath, the residue contained HgAg_{13} ; in a mercury vapour-bath, HgAg_{11} ; and in a diphenylamine-bath, HgAg_4 ; and V. Merz and W. Weith found that if the amalgam be heated in a sulphur vapour-bath for 21, 72, and 100 hrs. there remains respectively 2.3, 1.26, and 1.24 per cent. of silver, and in a diphenylamine-bath for 50 and 78 hrs. there remains respectively 5.4 and 4.4 per cent. of silver. At 200° in a stream of air, G. A. Hulett obtained a distillate with one part of silver in 533,000 parts of mercury; after a second distillation, 0.03 part of silver in 1,000,000 parts of mercury; and after a third distillation, no silver could be detected in the distillate. With very carefully regulated heating, D. J. A. Schlosser obtained the residual silver in a dendritic form. C. Brame made a similar observation with respect to silver amalgam as that which he made with respect to silver. C. Hockin and H. A. Taylor made a **silver-copper amalgam**, and measured its e.m.f. against amalgamated zinc or dil. sulphuric acid. The so-called *dental amalgam*, studied by A. W. Gray, is an alloy of silver and tin with may be 5 per cent. copper. For use it is mixed with mercury.

Gold amalgams.—The remarks concerning the early history of silver amalgam are also applicable to gold amalgam. In 1783, J. B. L. Romé de l'Isle⁴ reported quadratic prisms of native *gold amalgam*. R. F. Marchand described a sample from Columbia, and, according to F. Schmitz, samples have been reported from almost all districts where gold occurs. Analyses range from 38.39 to 41.63 per cent. of gold; 57.40 to 60.98 per cent. of mercury; and with up to 5 per cent. of silver. The formula Au_2Hg_3 has been applied to many native gold amalgams.

According to W. Guertler,⁵ the solubility of gold in solid mercury is small. A. Gouy measured the solubility of gold in mercury, and found the solubilities of copper, silver, and gold to be 0.00001, 0.0003, and 0.0013 part of metal per unit weight of amalgam. M. von Wogau found the diffusion coeff. of gold in mercury to be $k = 8.33$ cals. per sq. cm. per sec. at 11° ; while W. C. Roberts-Austen found the diffusion coeff. of mercury in gold to be $k = 0.72$ at 11° . Gold amalgam is slowly

formed by mixing its constituents at ordinary temp., but more rapidly if the temp. is raised—say, by putting red-hot gold plates into mercury. J. F. Daniell stated that a bar of gold dipped in cold mercury quickly turns white, and is soon completely penetrated by mercury, but even after a month the gold remains malleable and is covered by small crystals. With boiling mercury, the gold dissolves, forming a mass with a pasty consistency. M. Faraday, and C. Barfoed noted the volatilization of mercury from the amalgam. W. Skey noted that some grains of native gold resist amalgamation because they are covered with a film of sulphide. The production of amalgam in the extraction of gold has been previously discussed. L. Knaffl recommended precipitated gold for the preparation of amalgams; T. Wilm used dil. sodium amalgam in place of mercury, and washed the product with conc. nitric acid. J. H. Croockewit prepared crystals of what he regarded as Hg_2Au by amalgamation and filtration by pressure through leather. T. H. Henry prepared four-sided prisms of what he regarded as HgAu_8 by dissolving one part of gold in 1000 parts of mercury and filtering the soln. through leather. E. de Souza obtained HgAu_8 or 9 as a residue after heating the amalgam in the diphenylamine vapour-bath; and HgAu_9 , by heating the amalgam in a bath of sulphur or mercury vapour. C. Paal and H. Steyer prepared **colloidal gold amalgam**.

The amalgam with 6 parts of mercury and one of gold crystallizes in four-sided prisms. A. H. Chester obtained hexagonal prismatic crystals by the action of mercury on gold and by dissolving out the excess of mercury with dil. nitric acid. T. Wilm's process furnishes acicular or columnar crystals. W. Ramsay measured the lowering of the vap. press. of mercury by gold, and G. Tammann, the lowering of the f.p. The results in both cases agree with monatomic mols. E. D. Eastman and J. H. Hildebrand measured the vap. press. of gold amalgams at conc. up to 23.7 per cent. of gold. The separation of a solid occurs at a conc. of 16.5 per cent. of gold. With more dil. soln. the vap. press. are greater than accord with Raoult's

FIG. 46.—Freezing-point Curves of Gold Amalgams.

law. E. Beckmann and O. Liesche found that the b.p. of gold amalgam agrees with the presence of monatomic uncombined gold. N. Parravano made a thermal diagram of amalgams with 0 to 35 per cent. of gold, and obtained a horizontal line at 100° , which was taken to correspond with a reaction between a solid, separating at a higher temp., and the liquid to form a new solid stable at a lower temp. S. A. Braley and R. F. Schneider obtained the results shown graphically in Fig. 46. There are thus two eutectics, and three compounds, **gold hemimercuride**, Au_2Hg , **gold pentamercuride**, Au_2Hg_5 , and **gold tetramercuride**, AuHg_4 . A. Matthiessen and C. Vogt, and N. Parravano and P. Jovanovich measured the electrical conductivity of gold amalgams, and found the conductivity at the gold end of a series with less than

10 per cent. of mercury decreases as the proportion of mercury increases. A. Coehn and A. Lotz found gold amalgam in vacuo is positively charged with respect to glass.

If gold amalgam be strongly heated, the mercury distils off, and if the rise of temp. be carefully regulated, the gold remains in an arborescent form; L. Knaffl obtained crystals of gold by heating the amalgam to 80° . According to E. de Souza,

if heated to the b.p. of sulphur, or mercury, until the weight is constant, the composition approximates to HgAu_9 , and to HgAu_3 in a bath of diphenylamine. V. Merz and W. Weith found the weight alters with time so that the amalgam contains 1.07 per cent. of mercury after heating 20 hrs. in a bath of sulphur vapour, 0.40 per cent. after 44 hrs.; and 0.33 per cent. after 60 hrs. Similarly, after 24 hrs. in a mercury vapour-bath there remain 2.63 per cent. of mercury; 1.75 per cent. after 75 hrs.; 1.48 per cent. after 114 hrs.; and 1.43 per cent. after 134 hrs. Likewise also in a bath of diphenylamine vapour there remains 7.86 per cent. of mercury after 24 hrs.' heating; 5.3 per cent. after 48 hrs.; and 4.5 per cent. after 75 hrs. G. A. Hulett distilled a sat. gold amalgam and found the distillate had 0.027 part of gold per 1,000,000 parts of mercury; and after repeated distillation only 0.01 part per million.

G. Kasanzeff found the composition of gold amalgam remaining after the action of nitric acid on the liquid amalgam depends on the temp. and conc. of the acid. The yellow or brown residues contain 8.4–18.4 per cent. of mercury. W. Ramsay said that gold amalgam is not very soluble in mercury. J. H. Croockewit found the sp. gr. of crystals of Hg_2Au to be 15.142; F. L. Sonnenschein gave 15.47 for Hg_3Au_2 . A. Wehrle prepared a mixed gold-silver amalgam, and R. F. Schneider regarded pieces of a mixed amalgam which he obtained from Columbia as containing $\text{Hg}_6(\text{Au}, \text{Ag})$; W. H. Seamon gave the composition $\text{Au}(\text{Hg}, \text{Ag})_2$. C. Hockin and H. A. Taylor measured the e.m.f. of a mixed amalgam against amalgamated zinc in dil. sulphuric acid.

§ 41. The Amalgams of the Metals of the Alkaline Earths

According to L. Maquenne,¹ the affinity of calcium for mercury is small. H. Iggena measured the solubility of barium and strontium in mercury at different temp., and found:

	0°	20°	30°	46°	56°	64.5°	81°	89.5°
Ba . . .	0.144	0.325	0.422	0.519	0.680	0.832	0.967	1.06 per cent.
Sr . . .	0.733	1.04	1.27	1.35	1.51	1.79	1.80	1.0 „

H. Moissan and G. Chavanne found that calcium dissolves but slowly in mercury at ordinary temp., and by shaking the two elements in an atm. free from moisture, a soln. containing 2.5 grms. of calcium per 100 grms. of mercury can be obtained. H. P. Cady, too, heated the two elements up to the b.p. of mercury, and found only a small proportion of calcium was dissolved. M. von Wogau measured the diffusion coeff. k in calcs. per sq. cm. per sec., and found for calcium at 10.2° $k=6.45$; for strontium at 9.4° , $k=5.44$; and for barium at 7.8° , $k=6.02$.

The preparation of amalgams of the alkaline earths.—H. Moissan and G. Chavanne prepared calcium amalgam by shaking 2 grms. of calcium with 100 grms. of mercury in an evacuated sealed tube for 24 hrs. R. Böttger prepared the amalgam of barium and strontium, and C. Klauer that of calcium by immersing one per cent. potassium or sodium in an aq. soln. of the alkaline earth chloride; the reaction is accompanied by a feeble evolution of gas. The amalgam is removed from the soln. as soon as the evolution of gas has ceased; dried by press. between bibulous paper; and preserved under rock oil. G. McP. Smith, W. Crookes, J. Schumann, H. Iggena, employed the process for barium amalgam; and G. McP. Smith and B. Franz, for strontium amalgam.

H. Davy prepared barium and strontium amalgams by moulding a mixture of the hydroxide, chloride, carbonate, or sulphate with water to form a kind of dish; placing the vessel on a platinum plate to serve as anode; filling the vessel with mercury, and using that as cathode. H. Davy, and J. J. Berzelius and M. M. Pontin likewise prepared calcium amalgam by similarly electrolyzing the hydroxide. R. Hare described the preparation of amalgams of the alkaline earths by what he called J. J. Berzelius and M. M. Pontin's process, *i.e.* the electrolysis of aq. soln. of their chlorides, in contact with mercury as cathode. This was one of the early applications of the mercury cathode which was introduced later in analytical work by W. Gibbs. The method was later employed by G. McP. Smith and H. C. Bennett, and P. M. Giesy and J. R. Withrow, who improved many details. R. Bunsen electrolyzed a mixture of barium chloride with a little dil. hydrochloric acid with a mercury cathode. L. Maquenne, H. Iggena, W. Kerp and co-workers, G. Langbein, and G. McP. Smith and co-workers similarly electrolyzed a soln. of the nitrate with a mercury cathode. Strontium and barium amalgams were prepared in a similar way by A. Guntz and G. Röderer, G. McP. Smith and co-workers, H. Iggena, P. Fedotieff, L. Maquenne, W. Kerp and co-workers, and G. Langbein. S. B. Frank and J. R. Withrow prepared solid strontium amalgam by electrolysis, but the same process did not succeed with calcium amalgam. W. Ramsay said that strontium or calcium amalgam prepared by electrolysis is very dil., since it is very readily attacked by water even when the electrolytic cell is surrounded by a freezing mixture. R. Bunsen made calcium amalgam by the process he used for barium amalgam. K. Bornemann and G. von Rauschenplat electrolyzed a soln. of calcium chloride with a carbon anode and mercury cathode. W. Kerp and co-workers, G. Langbein, H. Iggena, L. Maquenne, etc., did not succeed so well with the electrolytic preparation of calcium amalgam as with the amalgam of barium and strontium. H. P. Cady obtained a dil. amalgam by the electrolysis of a boiling soln. of calcium chloride; H. G. Byers also used a soln. of the chloride. J. Féréé used a cell with a diaphragm and a mercury cathode. G. McP. Smith and co-workers electrolyzed a sat. soln. of calcium acetate. B. S. Neuhausen employed the electrolytic process. L. Maquenne concentrated the dil. amalgams by distillation in vacuo; and A. Guntz and co-workers, G. Langbein, W. Kerp and co-workers, and H. Iggena, by distillation under reduced press. in a stream of hydrogen.

A. Guntz and J. Féréé reported that crystals of **barium hexadecamercuride**, BaHg_{16} , are formed by pressing the electrolytically prepared amalgam through leather, but neither G. Langbein, nor H. Iggena could obtain such a compound,

and W. Kerp considers that the alleged compound is a mixture of BaHg_{12} and mercury. Similar remarks apply to the **strontium tetradecamercuride**, SrHg_{14} , likewise to **barium tridecamercuride**, BaHg_{13} , reported to be formed as a solid phase at a temp. not exceeding 30° :

		0°	20°	25°	27.6°	28.1°	29.2°	
Ba in liquid	.	0.15	0.32	0.34	0.35	0.36	0.38	per cent.
Ba in solid	.	4.60	4.73	4.93	4.75	4.77	4.80	„

The calculated value for BaHg_{13} is 5 per cent. Ba. H. Iggena, and W. Kerp and co-workers obtained similar evidence for **barium dodecamercuride**, BaHg_{12} , above 30° :

		30°	46°	56°	65°	81°	99°	
Ba in liquid	.	0.43	0.52	0.68	0.83	0.97	1.26	per cent.
Ba in solid	.	5.29	5.23	5.26	5.26	5.26	5.34	„

The calculated value for BaHg_{12} is 5.39 per cent. Ba. Similar evidence was obtained for **strontium dodecamercuride**, SrHg_{12} , between 0° and 30° :

		0°	20°	30°	46°	64.5°	81°	
Sr in liquid	.	0.73	1.02	1.25	1.33	1.76	—	
Sr in solid	.	3.40	3.33	3.42	3.98	5.33	5.37	

when the calculated value for SrHg_{12} is 3.51 per cent. Sr. The strontium salt is stated by W. Kerp and co-workers to crystallize from soln. of any conc. at room temp. The silvery plates begin to decompose at 60° under petroleum, and melt at 70° . G. McP. Smith and H. C. Bennett also prepared these crystals as well as those of Hg_{12}Ba by centrifuging off the excess of mercury. H. Iggena, and W. Kerp and co-workers made the barium salt by crystallization between 30° and 100° ; and A. Guntz and J. Féréé by squeezing BaHg_{16} at 200 kgrms. per 5 sq. cm. The crystals of the barium salt are cubic. They do not melt when heated in air, but are energetically oxidized; they are decomposed by water.

W. Kerp obtained a mixture of a liquid and solid amalgam by keeping electrolytically prepared strontium amalgam for some time from which a product thought to be **strontium henamercuride**, SrHg_{11} , was obtained. A. Guntz and G. Röderer separated the two by a centrifuge. G. Langbein also prepared this product. H. Iggena, and W. Kerp and co-workers regarded it as a mixture of the dodecamercuride and a decomposition product from which all the free mercury has not been removed. A. Guntz and J. Féréé said it is formed when the tetradecamercuride is subjected to a press. of 200 kgrms. per sq. cm. The crystals, according to G. Langbein, furnish cubes and needles, which, according to A. Guntz, are triclinic, and have the m.p. 125° . They are said to change rapidly on exposure to air, forming a mixture of mercury, mercurous oxide, and strontium oxide and carbonate; they can be preserved in a dry atm. free from carbon dioxide; they are decomposed by water, but not so easily as the liquid amalgam; and when heated in vacuo, mercury begins to distil off at about 150° leaving a residue with the composition Hg_5Sr_2 . G. Langbein prepared cubic crystals of **barium henamercuride**, BaHg_{11} , which melted at 165° , and behaved like the strontium compound.

H. Moissan and G. Chavanne prepared hexagonal prisms of **calcium octomercuride**, CaHg_8 , which did not melt when heated in vacuo, but the mercury distilled off, forming an amalgam richer in calcium. H. Iggena, and W. Kerp and co-workers prepared what was supposed to be either **strontium octomercuride**, SrHg_8 , or the heptamercuride, SrHg_7 , from the amalgam at about 64° – 81° . A. Guntz and G. Röderer obtained hexagonal plates of **strontium hexamercuride**, SrHg_6 , by distilling mercury from the henamercuride. J. Schürger prepared **calcium pentamercuride**, CaHg_5 , by heating a mixture of calcium with mercury in an atm. of carbon dioxide at 200° – 220° . The compound crystallizes in rhombic prisms or needles. It is a reducing agent, is unaltered at the ordinary temp. by dry hydrogen, nitrogen, or nitrous oxide, and oxidizes slowly in dry air but very quickly in moist air. When heated with dry ammonia at the b.p. of mercury, it is converted into a mixture

of calcium hydride and nitride, which decomposes violently in contact with water, with evolution of hydrogen and ammonia. When heated with nitrous oxide, it is converted into calcium oxide without the formation of nitride or nitrosyl calcium. When heated with phosphine, it yields calcium phosphide and a yellow sublimate of mercury phosphide. A. Guntz and G. Röderer, H. Iggena, and W. Kerp and co-workers obtained **strontium pentahemimercuride**, Sr_2Hg_5 , as a residue in the distillation of mercury amalgam. J. Férée prepared **calcium tetratritamercuride**, Ca_3Hg_4 , in a similar way. The amalgam is porous and greenish-white; it readily decomposes water. When heated in an atm. of hydrogen, it loses mercury but does not form calcium hydride at 400° ; the amalgam is rapidly decomposed by nitrogen at 400° ; and it blackens when exposed to air at ordinary temp. owing to the fixation of both oxygen and nitrogen. The only mercuride revealed by L. Cambi and G. Speroni's thermal study of calcium amalgam is **calcium tetramercuride**, CaHg_4 , melting with decomposition at 266° . At higher temp. there is evidence of a primary separation into mercury and **calcium dimercuride**, CaHg_2 . G. Langbein inferred from the sp. vol. curve the existence of **strontium monomercuride**, SrHg , and **barium monomercuride**, BaHg , in the respective liquid amalgams. G. McP. Smith obtained evidence of the formation of CaHg_5 and BaHg_6 from the study of the diffusion constants, and of the surface tension of amalgams.

The properties of the amalgams of the alkaline earths.—G. Langbein stated that strontium amalgam adheres to glass better than barium amalgam. Some chemical properties of the amalgams of the alkaline earths have been indicated above. G. Langbein said that the **coefficient of thermal expansion** of strontium amalgam, $\alpha = 0.000181 + 0.000008w$, when w is the percentage by weight of strontium, is not very different from that of mercury alone; similarly with barium amalgam, where $\alpha = 0.000181 + 0.000023$. Mixtures containing over 14 at. per cent. of calcium were found by L. Cambi and G. Speroni to have a **melting point** above the b.p. of mercury at ordinary press. W. Ramsay measured the **vapour pressure** of calcium in mercury and obtained a mol. wt. of 19.0 (theory, 40.08); and for barium 75.7 (theory, 137). E. Beckmann and O. Liesche found the effect of calcium on the b.p. of mercury corresponding with the formation of **calcium decamercuride**, CaHg_{10} , at these temp. K. Bornemann and G. von Rauschenplat obtained for the **specific resistance**, R , and **specific conductivity**, C , of a 0.12 per cent. calcium amalgam at 0° :

	50°	100°	150°	200°	250°	300°
$R \times 10^4$. .	0.9702	1.0178	1.0680	1.1250	1.1843	1.2600
$C \times 10^{-4}$. .	1.0307	0.9285	0.9363	0.8897	0.8444	0.7937

with a temp. coeff. 0.1032×10^{-6} between 50° and 200° ; and 0.1350×10^{-6} between 200° and 300° . H. P. Cady, A. Schöller, M. le Blanc, and G. McP. Smith measured the **electromotive force** of amalgams of the alkaline earths—the latter found for 0.0439 per cent. calcium amalgam at 23° in 0.1N-LiCl, 1.2 volt against 0.088 per cent. strontium amalgam, and 0.107 volt against 0.1385 per cent. barium amalgam; and the same strontium amalgam against the barium amalgam 0.08 volt. L. Cambi measured the e.m.f. of calcium amalgams in methyl alcoholic soln. of calcium chloride at -80° . There is evidence of an abrupt increase in voltage corresponding with CaHg_4 , and a less marked increase with **calcium enneamercuride**, CaHg_9 . There is no evidence of the latter on the fusion curve because its temp. of formation is near -41° when the two arrests in the cooling curve are superposed. L. Cambi made similar measurements with pyridine soln. at 25° . S. B. Frank and J. R. Withrow studied the electro-endosmosis of calcium amalgam.

According to J. J. Berzelius and M. M. Pontin, when calcium amalgam is exposed to air it is soon covered by a black film of mercurous and calcium oxides; but, according to H. Moissan and G. Chavanne, the film is mercury and calcium oxide. The amalgam is stable in dry air reacting neither with nitrogen nor oxygen. W. Ramsay, J. Férée, and G. McP. Smith have also noted the instability of calcium

amalgam in air; and L. Maquenne found it to be more readily oxidized than strontium amalgam. B. Franz found strontium amalgam to be less stable than barium or sodium amalgam when exposed to air, and W. Ramsay, H. Iggena, G. Langbein, and G. McP. Smith have shown the ready oxidation of this amalgam in air. A. Guntz and G. Röderer said that 6–10 per cent. strontium amalgams are not much affected by exposure to air. J. J. Berzelius and M. M. Pontin, R. Böttger, G. Langbein, H. Iggena, W. Kerp and co-workers, and J. Schumann noted the oxidation of barium amalgam in air. L. Maquenne said that a 25 per cent. barium amalgam oxidizes rapidly in moist air with the development of much heat, but it may be preserved in vacuo or in an inert gas. Calcium amalgam is to be kept in an atm. of **hydrogen** or **carbon dioxide**. *Vide supra* for the action of hydrogen on calcium amalgam. B. Franz said strontium amalgam furnishes strontium when heated in a stream of hydrogen. A. Guntz found that barium amalgam forms barium hydride, BaH_2 , of a high degree of purity when heated in an atm. of hydrogen in an iron vessel to 1400° , and strontium amalgam requires a higher temp. to form the hydride. J. J. Berzelius and M. M. Pontin, and H. Moissan and G. Chavanne found that calcium amalgam is slowly decomposed by **water**, forming mercury, calcium hydroxide, and hydrogen; G. McP. Smith found that calcium amalgam is attacked by water more readily than strontium or barium amalgam. H. Iggena, and W. Kerp and co-workers noted the decomposition of water by strontium amalgam—G. Langbein said that with a 27 per cent. strontium amalgam, or a 33 per cent. barium amalgam, the attack is vigorous, and L. Maquenne that a 25 per cent. barium amalgam attacks water rapidly. According to H. Moissan and G. Chavanne, aq. soln. of **mineral acids** attack calcium amalgam like they do sodium amalgam; it reduces an aq. soln. of **alkali nitrate** to ammonia and a trace of nitrite. L. Maquenne found that barium amalgam has scarcely any reducing action on an aq. soln. of **sodium nitrite**. H. Moissan and G. Chavanne found that when calcium amalgam is treated with a soln. of **ammonium sulphate**, ammonium amalgam is formed. R. Böttger also noted the formation of ammonium amalgam when barium amalgam is treated with a soln. of **ammonium chloride**. H. G. Byers also noted the reaction of calcium amalgam as an electrode with soln. of alkali nitrate, **potassium chloride**, or **barium chloride**; and there is an equilibrium condition between calcium amalgam, and **sodium salts** in which the formation of sodium amalgam is involved. G. Fernekes found that very little, if any, barium is replaced by alkali with soln. of sodium or potassium chloride; and G. McP. Smith found a soln. of hydroxide acts more quickly. According to R. Böttger, when a globule of amalgam is placed in a sat. soln. of **cupric sulphate**, it immediately begins to rotate, causing the soln. to move in two opposite directions, and at the same time, barium sulphate shoots out in flakes which assume various hues, from the presence of hydrated cuprous and cupric oxides, and have the appearance of a growth of moss; the action goes on 15–20 mins., by which time the barium is all converted into sulphate. L. Maquenne found that when calcium is heated in a stream of **nitrogen**, a grey amorphous mass is formed which furnishes ammonia when treated with water; according to J. Féréé, the product is calcium nitride; L. Maquenne obtained in a similar way strontium nitride and barium nitride—both free from mercury. J. J. Berzelius and M. M. Pontin did not succeed in amalgamating **iron** with calcium amalgam. H. Moissan and G. Chavanne found that calcium amalgam transforms **acetone** into a mixture of isopropyl alcohol and pinacone; and that it does not act on **benzene** dissolved in a moist ether.

§ 42. The Amalgams of Beryllium and Magnesium

L. F. Nilson and O. Pettersson¹ prepared **beryllium amalgam** by the electrolysis of a conc. soln. of beryllium chloride with a mercury cathode. According to W. Ramsay, the amalgam so prepared is very dil., since more conc. amalgams are readily attacked by the electrolyte; and it is readily oxidized in air.

H. Davy² prepared **magnesium amalgam** by the electrolytic process used for barium amalgam, but, according to W. Kerp and co-workers, the electrolytic process is not satisfactory. A. A. B. Bussy stated that magnesium combines with mercury only when heated, forming a solid amalgam even with a large proportion of mercury. J. A. Wanklyn and E. T. Chapman stated that the two elements unite slowly in the cold, but rapidly and vigorously at the b.p. of mercury. T. Evans and W. C. Fetsch made an amalgam by triturating magnesium powder with 18 times its weight of mercury in a warm mortar. Silvery crystals approximating to Hg_2Mg separate from the amalgam so prepared. The two elements unite at ordinary temp.; the reaction starts slowly, but the heat which is evolved accelerates the reaction. J. Parkinson, W. Ramsay, J. Schumann, H. Fleck and L. L. Bassett, W. J. Humphreys, H. Iggena, W. Kerp and co-workers, and A. C. Christomanos employed modifications of these processes for the preparation of magnesium amalgam. L. Cambi and G. Speroni made amalgams by dissolving clean magnesium in mercury boiling in a Jena glass vessel in an atm. of nitrogen; and also by heating mixtures of the two elements in a sealed tube at 390°–400° for 36–48 hrs. Amalgams with more magnesium than the atomic ratio $Mg : Hg$ are difficult to get uniform. C. Klauer made it by the action of potassium amalgam on a soln. of magnesium sulphate, and J. Schumann used sodium amalgam. A. C. Christomanos said that, unlike zinc, copper, and platinum, magnesium is not amalgamated by sodium or ammonium amalgam except sporadically after rubbing the metal with the amalgam for a long time. A. Schmidt and K. Seubert passed the vapour of mercuric chloride over molten magnesium, and also heated a mixture of mercurous chloride and magnesium filings.

H. Iggena, and W. Kerp and co-workers separated crystals of what they regarded as **magnesium hexamercuride**, $MgHg_6$, by rapidly filtering magnesium amalgam. P. I. Bachmetjeff and J. V. Wsharoff thought that **magnesium tetramercuride**, $MgHg_4$, probably exists since the sp. ht. of this amalgam is greater than corresponds with the mixture rule. As indicated above, T. Evans and W. C. Fetsch obtained an amalgam corresponding with **magnesium dimercuride**, $MgHg_2$. L. Cambi measured the e.m.f. of magnesium amalgams and soln. of magnesium chloride and iodide in methyl alcohol at -80° , and in pyridine, and found an abrupt

change in the curve corresponding with MgHg_2 . R. P. Beck measured the potential differences of magnesium amalgams in 0.1982*N*-soln. of magnesium chloride in ethyl alcohol.

According to H. Fleck and L. L. Bassett, amalgams with 2 per cent. of magnesium are solid and crystalline; and R. S. Willows stated that an amalgam with less than one per cent. of magnesium was solid, and possessed a **melting point** of 170° . L. Cambi and G. Speroni found that the m.p. of an amalgam with 30 per cent. of Mg is higher than the b.p. of mercury. L. Cambi and G. Speroni's thermal study of these amalgams showed the presence of MgHg_2 , melting with decomposition at 168° ; but they did not follow the curve past MgHg . They considered the analogies in the binary systems Ca—Hg and Mg—Hg. A. Smits and R. P. Beck explored the

FIG. 47.—Fusion Curves of Magnesium Amalgams.

curve for the change of **electrical resistance** with temp. of one per cent. amalgam, is practically a straight line up to 110° , and above that temp. the increase of the resistance is slightly faster than the rise of temp. Unlike the results with zinc and cadmium amalgams, the resistance is the same whether the metal is being heated or cooled. M. le Blanc, R. Kremann and R. Müller, G. Babarovsky, L. Cambi, R. P. Beck, and G. Gore measured the **electromotive force** of magnesium amalgams.

According to J. A. Wanklyn and E. T. Chapman, an amalgam with 0.5 per cent. of magnesium swells up and becomes matt when exposed to **air**, but, added W. J. Humphreys, the amalgam is not attacked by dry air. G. le Bon found that $\frac{1}{14000}$ th part of magnesium in mercury is oxidized in air; and G. Gore found that an amalgam with $\frac{1}{1605}$ th of magnesium is quickly covered by a black layer of what he regarded as magnesium suboxide, but this is more probably a mixture of mercury and magnesia. J. Parkinson, W. Ramsay, H. Iggena, and W. Kerp and co-workers also noted how quickly magnesium is oxidized when amalgamated with mercury. H. Davy stated that magnesium amalgam is slowly oxidized by **water**, and rapidly by acidulated water. When mercury is amalgamated with magnesium it acquires the property of decomposing water at ordinary temp.; according to G. le Bon, $\frac{1}{14000}$ th of magnesium has an appreciable influence, and magnesium contaminated with mercury also decomposes cold water rapidly. J. Schumann, A. C. Christomanos, H. Iggena, J. Parkinson, T. Evans and W. C. Fetsch, and W. Kerp and co-workers have made observations on this subject. J. A. Wanklyn and E. T. Chapman said that 0.5 per cent. magnesium amalgam decomposes water faster than one per cent. sodium amalgam. T. Evans and W. C. Fetsch observed that

m.p.-composition curves, Fig. 47, and found magnesium dimercuride, MgHg_2 ; **magnesium mercuride**, MgHg ; **magnesium dritramercuride**, Mg_3Hg_2 ; **magnesium hemimercuride**, Mg_2Hg ; **magnesium tritramercuride**, Mg_3Hg ; and possibly **magnesium trihemimercuride**, Mg_2Hg_3 ; but not the hexa- and tetra-mercurides. R. P. Beck also discussed this subject; the existence of R. Kremann and R. Müller's *magnesium decitamercuride*, HgMg_{10} , was disproved. P. I. Bachmetjeff and J. V. Wsharoff observed no definite m.p. with the solid amalgams; they also made observations on the **specific heat**. R. P. Beck measured the **vapour pressure** of magnesium amalgams; and W. Ramsay determined the lowering of the vap. press. of mercury by magnesium and obtained a mol. wt. between 21.5 and 24.0 in agreement with the theoretical 24.3 for a monatomic molecule. E. Beckmann and O. Liesche studied the effect of magnesium on the b.p. of mercury. R. S. Willows found the

magnesium amalgam has scarcely any action on **alcohol**; but L. Meunier said that magnesium ethoxide is formed and hydrogen evolved with absolute alcohol. M. P. Voronkoff, V. E. Tischtschenko and A. A. Grigorjeff, and A. Kling and P. Roy studied the reducing action of magnesium amalgam on **aldehyde**; F. Couturier and L. Meunier on **acetone**; L. Bouveault and R. Locquin, on **dimethylketone**; H. Fleck, on **alkyl iodides**; T. Evans and co-workers, and M. Chavassieu, on aromatic **nitro-derivatives**. A. G. Loomis studied the ternary system Mg-Hg-NH_3 .

§ 43. The Amalgams of Zinc and Cadmium

The solubility of cadmium is much greater than that of zinc in mercury. H. Iggena ¹ found the solubilities of zinc and cadmium in mercury to be:

	0°	25°	35°	56°	64·5°	73°	99°
Zn . . .	1·63	2·15	—	3·20	3·49	—	4·73 per cent.
Cd . . .	3·27	5·92	7·52	11·53	—	15·89	24·42 „

The presence of copper did not influence the solubility of zinc in mercury. A. Gouy also measured the solubilities between 15° and 18°, and found 0·018 and 0·040 for the ratio of the amount of zinc or cadmium dissolved to the total weight. W. Kerp and co-workers found these numbers too small. J. L. Crenshaw gave 2·2199 grms. per 100 grms. of mercury for the solubility of zinc at 25°; and G. A. Hulett and R. E. de Lury, 5·574 grms. per 100 grms. of mercury for the solubility of cadmium at 25°. W. J. Humphreys measured the velocity of diffusion of zinc in mercury; and M. von Wogau found for $k \times 10^{-6}$ in grms. per sq. cm. per sec. for zinc $k=25\cdot20$ at 11·5°, and 33·5 at 99·2°; and for cadmium, $k=16\cdot8$ at 8·7°, and 34·2 at 99·1°. F. G. Cottrell and G. Meyer also made measurements of this constant, and the latter found at 15°, for zinc and cadmium respectively 0·087 and 0·065 cal. per sq. cm. per hour.

The preparation of zinc and cadmium amalgams.—Zinc and cadmium unite with mercury at ordinary temp. Cadmium amalgam was first prepared by

F. Stromeyer.² Zinc amalgam is made by pouring a fine stream of mercury into molten zinc cooled as low as possible without solidification; the liquid is constantly stirred during the mixing. According to J. F. Daniell, when zinc filings are triturated with mercury at ordinary temp., combination is slow; but at a higher temp., below the b.p. of mercury, the metals readily unite, and still more so if the mercury is mixed with molten zinc. A zinc rod immersed half its length in mercury for ten days, becomes pointed at the bottom, and covered, especially on the upper part of the immersed end, with six-sided plates of amalgam. A. A. Damour, W. Ramsay, J. Regnault, J. Schumann, H. Kahle, T. W. Richards and co-workers, and H. S. Carhart and co-workers prepared zinc amalgams by dissolving the zinc in hot mercury; and J. Schumann, H. Iggena, K. Bornemann and G. von Rauschenplat, R. Frilley, W. J. Humphreys, W. Kerp and co-workers, and T. W. Richards prepared cadmium amalgam in a similar way.

T. W. Richards and G. S. Forbes made zinc or cadmium amalgam by shaking the two elements with dil. aq. ammonia in a stoppered vessel. H. N. Morse and W. M. Burton used dil. tartaric acid in place of the aq. ammonia. J. W. Döbereiner stated that when zinc is placed in contact with mercury and a dil. acid, a galvanic action is set up, and the zinc becomes covered with mercury which penetrates to the interior, and converts the whole of the metal into an amalgam. As soon as the zinc is quite covered with mercury, the evolution of hydrogen ceases, but it begins again on bringing the amalgam in contact with iron, copper, or platinum, to which metals the mercury is then transferred. A. C. Christomanos said zinc is uniformly amalgamated by ammonium amalgam. R. Böttger found that a soln. of zinc sulphate or cadmium sulphate furnishes the corresponding amalgam when treated with sodium amalgam. According to A. Bornträger, zinc is amalgamated when placed in a 10 per cent. soln. of mercuric chloride, but not in a soln. of mercuric nitrate. G. Oppermann amalgamated zinc by mixing a soln. of mercuric sulphate in dil. sulphuric acid with enough *N*-oxalic acid to make a thin paste; this was then mixed with a little ammonium chloride, and painted on the zinc.

H. Iggena prepared zinc amalgam by the electrolysis of a soln. of zinc sulphate with a mercury cathode; A. Schaag electrolyzed with a zinc anode a soln. of 6 kgrms. of zinc sulphate, 4 kgrms. of zinc chloride, or 8 kgrms. of zinc oxalate, in 100 litres of boiling water, and mixed with 150 grms. of mercuric chloride. H. Paweck, and E. Cohen and P. J. H. van Ginneken studied the preparation of zinc amalgams. H. S. Carhart, and W. Kerp and co-workers also electrolyzed soln. of cadmium salts

with a mercury cathode. C. Luckow precipitated zinc quantitatively as an amalgam by means of a mercury cathode. G. Vortmann prepared cadmium amalgam by the electrolysis of an aq. soln. of a zinc or cadmium salt with mercuric chloride and an excess of ammonium oxalate.

There is no evidence of any compounds of zinc and mercury on the f.p. diagram, Fig. 48, based on that prepared by N. A. Puschin. K. Bornemann's observations on the zones of mixed crystals are indicated diagrammatically by the stippled regions. There is a eutectic with about 4 at. per cent. of zinc, at -42.5° . J. H. Crockett obtained brittle crystals with the composition Zn_3Hg_2 ; F. C. Calvert and R. Johnson gave 11.304 for the sp. gr. of crystalline HgZn ; J. P. Joule gave 11.34; and J. P. Joule, Zn_2Hg , by squeezing the excess of zinc from the

FIG. 48.—Equilibrium Diagram of Zn-Hg Alloys.

amalgam. The evidence of the non-existence of definite compounds is confirmed by W. Kerp and co-workers, from observations on the solubility of zinc in mercury; by R. S. Willows' observations on the electrical resistance; by E. Maey's observations on the sp. vol.; and by various observations on the e.m.f. —*vide infra*.

R. Frilley's curves of the sp. gr., and E. Maey's curves for the sp. vol. of cadmium amalgams show breaks corresponding with the **cadmium mercurides**, Hg:Cd=12:1, 5:1, 7:2, 5:4, 1:2, and 1:8, as well as one intermediate between 1:2 and 1:4. The f.p. curves of H. C. Bijl, and K. Bornemann's zone of mixed crystals are shown in Fig. 49. The f.p. curve has also been studied by N. A. Puschin and E. Cohen. According to G. McP. Smith, mercury and cadmium do not form any compounds, and, according to G. A. Hulett, the two elements are miscible in all proportions at 210°.

According to W. Kerp and co-workers, and H. Iggena, the *dicadmium heptamercuride*, Cd_2Hg_7 , appears as a stable phase with soln. of cadmium in mercury between 0° and 40·5°.

FIG. 49.—Equilibrium Diagram of Cd—Hg Alloys.

	35°	38°	40·5°	56·8°	73°	89°	99°	
Cd in liquid	6·99	7·48	7·78	10·34	13·71	17·45	19·43	per cent.
Cd in solid	13·64	13·32	13·27	15·30	18·54	22·83	23·03	„
Solid phase	Hg_2Cd_3							

The product is obtained by filtering the excess of mercury from the crystalline mass. It is said to melt at 70°–75°, and to freeze at 60°. It is stable in air; it is not attacked by dil. hydrochloric acid, but is slowly attacked by the cold conc. acid, and rapidly by the hot conc. acid. N. A. Puschin doubted the individuality of this mercuride. J. H. Croockewit prepared crystals of what he regarded as *cadmium pentahemimercuride*, Hg_5Cd_2 , by dissolving cadmium in warm mercury, and squeezing out the excess of solvent. The sp. gr. was stated to be 12·615; J. Schumann gave 12·44, and stated that it is soft at 76°, and liquid at 90°, and that it expands 2·3 per cent. when heated from 20° to 145°. F. Stromeyer prepared octahedral crystals with a composition corresponding with *cadmium dimercuride*, CdHg_2 , and a sp. gr. greater than that of mercury. The m.p. was given as 75°. J. Schumann said that an amalgam of this composition has a sp. gr. 12·49 when the value calculated from the mixture law is 12·2; it forms a mush at 75°, and is liquid at 105°; and it expands 2·7 per cent. in passing from 20° to 145°. J. Schumann does not consider the product to be a chemical individual. G. Gore assumed that a *cadmium monomercuride*, HgCd , can be formed from eq. proportions of the two elements. J. Schumann said that an amalgam of this composition begins to soften at 130°, and is liquid at 140°; its sp. gr. is 11·367 when the mixture law indicates 11·345; and it expands 2·5 per cent. when heated from 20° to 145°. E. Jänecke prepared *sodium cadmium mercuride*, NaCdHg , of m.p. 325°.

The physical properties of zinc amalgams.—The solid amalgams are silvery-white, hard, brittle, crystalline masses which, according to H. Iggena,³ and W. Kerp and co-workers, retain the mother liquid very tenaciously. A. Battelli said that the amalgams are liquid when the atomic proportion of Hg:Zn is greater than 8:1, and solid when less than 2:1. According to N. A. Puschin, the

microstructure shows hexagonal crystals to be present. The **specific gravity** was determined by J. P. Joule, etc. E. Maey found the sp. gr. and sp. vol. of zinc amalgams with w per cent. of zinc :

w . . .	0	1.68	1.99	7.34	9.77	39.47	48.6	100
Sp. gr. .	13.552	13.405	13.371	12.681	12.434	10.075	9.453*	7.087
Sp. vol. .	0.07379	0.07460	0.07479	0.07886	0.08043	0.09926	0.1058	0.1411

There is no evidence of breaks corresponding with the formation of definite compounds. J. L. Crenshaw represented the sp. gr., S , at 25° as a linear function of the amount of zinc, w , in 100 parts of mercury: $S=13.5340-0.0859w$. According to T. W. Richards and G. S. Forbes, zinc amalgams show a greater and greater contraction with increasing proportions of mercury owing probably to the formation of diatomic mols. E. Cohen and K. Inouye made electrometric and dilatometric observations, and found complications are produced by a transformation which E. Cohen and P. J. H. van Ginneken place at the **transition temperature**, 42.9° . H. S. Carhart also observed a transition point in a 2.3 per cent. zinc amalgam. E. von Schweidler found the coeff. of **viscosity** of 0.6 per cent. zinc amalgam to be $0.01639-0.00300\theta+0.0000059\theta^2$. G. Meyer measured the **surface tension** of zinc amalgams.

According to R. S. Willows, the **thermal expansion** of zinc amalgams up to 36° , is proportional to the temp., and beyond that it increases faster than the rise of temp., but although the electrical resistance changes abruptly at this temp., there is no abrupt change in the rate of expansion. When the temp. is falling, the vol. of the amalgam is greater than when it is rising. No irregularities were observed in the rate of cooling corresponding with those at which the electrical resistance changes abruptly. The **melting points**, or f.p., of zinc amalgams have been determined by C. Cattaneo, P. I. Bachmetjeff and J. V. Wsharoff, L. Schüz, A. A. Damour, E. Cohen and K. Inouye, and N. A. Puschin. The results by the last-named are indicated in Fig. 47. G. Tammann measured the **lowering of the freezing point** of mercury by zinc; and T. W. Richards and G. N. Lewis found that amalgams with less than one per cent. of zinc behave like dil. soln. J. H. Hildebrand measured the **vapour pressure** of zinc amalgams, and W. Ramsay showed that the molecular **lowering of the vapour pressure** of mercury by zinc corresponds with a mol. wt. of 62.1 to 70.1—theory, 65.43. G. A. Hulett found that the vap. press. of an amalgam with one part of zinc to 10^8 parts of mercury at 210° is at least 3×10^7 as great as that of zinc vapour at that temp. By the **boiling point** method of determining mol. wt., E. Beckmann and O. Liesche found zinc is present in the monatomic form at the b.p. of the amalgam. L. Schüz gave 0.05418 for the **specific heat** of Zn_3Hg_4 ; 0.05528, for ZnHg ; and 0.06705, for Zn_2Hg . J. Marttinen and J. R. Tiihonen, measured the sp. ht. of zinc amalgams. F. C. Calvert and R. Johnson gave 304.1 for the **thermal conductivity** of the amalgam Zn_2Hg , when the value calculated from the law of mixtures is 281.2—silver, 1000. They also found 327.6 for Zn_3Hg —calc. 315.0; 344.9 for Zn_4Hg —calc. 378.7; and 437.3 for Zn_5Hg —calc. 409.1. J. Regnaud found that the zinc amalgamation of zinc is attended by the absorption of heat. W. D. Henderson measured the heat of dilution of zinc amalgam. P. A. Favre found the **heat of solution** of amalgamated zinc in mercury is 394 Cals., and that of zinc, 373.4 Cals., thus making -21 Cals. for the **heat of amalgamation**. T. W. Richards and G. N. Lewis found -2.255 Cals. for the heat of amalgamation of a gram-atom of zinc in 6500 grms. of mercury.

A. Matthiessen and C. Vogt measured the **electrical conductivity** of zinc amalgam; G. G. Gerosa, C. L. Weber, A. Battelli, E. von Schweidler and R. S. Willows, the **electrical resistance**. A. Larsen found for the conductivity, C , of amalgams with w parts of zinc in 1000 parts of mercury between 15.9° and 20.1° referred to that of mercury at the same temp.;

<i>w</i>	.	.	0.095	0.853	2.752	4.904	8.219	12.42	16.32	19.16

According to R. S. Willows, the curve for the electrical resistance of 4-40 per cent. zinc amalgams, after repeated heating and cooling, is quite different from the original values. The curves, Fig. 50, were obtained with a 4.8 per cent. zinc amalgam, and the direction of the arrows shows whether the temp. is rising or falling. The curve *A* was obtained with freshly prepared amalgam, and *B* with the same amalgam after standing 4 weeks. Starting from 15°, the resistance, *A*, gradually falls as the temp. rises to 30°; between 30° and 40°, it scarcely alters; and thereafter rises with the temp. On cooling the resistance falls more rapidly than the temp., so that the cooling curve lies below the heating curve, and cuts the latter at 28°, so that the final resistance is usually very slightly greater than it was at the beginning. When repeated a number of times, the cooling curve becomes virtually coincident with *A*; and after standing some weeks the curve obtained is again like *B*. With amalgams containing over 10 per cent. of zinc the two curves almost coincide above 40°. According to R. S. Willows, the amalgam may be regarded as a mixture of zinc, mercury, and compounds of the two elements. As the temp. rises to 36°, one of the compounds becomes unstable, and either the compound is wholly or partially dissociated, or a new and more stable compound is formed. If the latter occurs there will be an absorption of heat, for something eq. to soln. in an excess of mercury must also occur; above 36°, the temp. coeff. is less, in accord with the fact that the temp. coeff. of an alloy is usually less than that of the pure metals, so that if zinc is liberated at this temp., the temp. coeff. ought to be expected to increase. The observed increase points to combination taking place or else to the dissociation of the compound into two others whose temp. coeff. are unknown. As the amalgam cools, the same compounds remain until the dissociation point is reached and heat is then evolved, and the resistance is increased. The dissociation is not completed when the initial temp. is reached unless the substance is cooled very slowly. The compound is unstable at ordinary temp. and a gradual dissociation occurs, accompanied by a fall in resistance, which extends over several weeks, finally reaching *O*, Fig. 50. If the amalgam is heated before this gradual change has taken place, there is no instability at 36°, and no abrupt change in resistance at that point.

FIG. 50.—Electrical Resistance of an Amalgam with 4.8 per cent. of Zinc.

A. Coehn and A. Lotz⁴ found that zinc amalgam in vacuo is negatively charged with respect to glass. According to H. Davy, zinc amalgam is more electropositive than zinc. A. Gauguain studied the position of zinc amalgam in Volta's series. S. Lindeek, T. W. Richards and G. N. Lewis, and A. Crova found that the **electromotive force** of mercury is very sensitive to a little zinc, so that the amalgam behaves almost like zinc itself. V. Rothmund found that 0.06 per cent. zinc amalgam has a potential of 0.587 volt in molar sulphuric acid containing 0.01 mol of zinc sulphate per litre. H. F. Weber measured the e.m.f. of zinc amalgam in conc. cells of zinc sulphate; and F. J. Mellankamp in conc. cells of zinc chloride.

W. Kistiakowsky, N. A. Puschin, J. F. Spencer, M. Berthelot, and J. H. Hildebrand measured the e.m.f. of zinc amalgam against zinc sulphate; J. L. Crenshaw, G. A. Hulett and H. D. Minchin, T. W. Richards and co-workers, H. S. Carhart, W. D. Henderson, and E. Cohen and co-workers, the e.m.f. of amalgams with different proportions of zinc against soln. of zinc sulphate.

E. Kittler measured the e.m.f. of zinc amalgam against sulphuric acid and copper; C. Wheatstone, against copper and cupric sulphate, copper and cupric nitrate, and in dil. sulphuric acid against lead or manganese dioxide; J. Regnaud and J. M. Gaugain, against copper and sulphuric acid with cells fitted with various diaphragms. F. Petruschewsky, A. Crova, C. R. A. Wright, E. Cohen and co-workers, and C. Cattaneo also studied various forms of Daniell's cell with zinc amalgam; C. Hockin and H. A. Taylor of zinc amalgam against sulphuric acid or a soln. of zinc sulphate, and zinc. G. Baumgartner studied the e.m.f. of zinc amalgam with soln. of sulphuric acid, sodium, potassium, or ammonium chloride, and ammonium or sodium nitrate of different conc. F. Fuchs measured the e.m.f. of zinc amalgam in a soln. of zinc sulphate against copper with a soln. of cupric sulphate; and of zinc amalgam in a soln. of zinc nitrate against copper and a soln. of cupric nitrate. J. Regnaud, and E. Branley measured the e.m.f. of zinc amalgam and a soln. of zinc sulphate against copper and cupric sulphate, and cadmium and cadmium sulphate. J. P. Joule studied the e.m.f. of zinc amalgam in soln. of potassium hydroxide, sodium chloride or sulphate, or sulphuric acid against copper in cupric sulphate; and of zinc amalgam in sulphuric acid against copper in a soln. of potassium dichromate with and without sulphuric acid; zinc amalgam in a soln. of potassium hydroxide against iron, coke, or gold in nitric acid; A. Naccari and M. Bellati, zinc amalgam against coke in a soln. of chromic acid free from sulphuric acid; J. C. Poggendorff, of zinc amalgam against coke and nitric acid; coke or copper and chromic acid. Further studies have been reported, by W. L. Robb, G. Magnanini, G. Gore, M. le Blanc, G. Meyer, H. P. Cady, A. Harrison, M. Jégou, C. Christiansen, E. Warburg and B. Strasser, etc. H. S. Taylor and G. St. J. Perrott measured the e.m.f. of cadmium amalgam against soln. of cadmium chloride and iodide.

G. Mayr studied the electrolysis of zinc amalgams. The hydrogen polarization and over-voltage with zinc amalgams have been studied by E. Cohen and W. A. Caspari, J. Roszkowsky, etc. A. Battelli said that electrodes of zinc amalgam are unpolarizable in soln. of zinc sulphate. The thermoelectric force of zinc amalgam with soln. of zinc salts has been investigated by C. L. Weber, E. Bouty, and R. S. Willows.

The physical properties of cadmium amalgams.—According to R. Frilley,⁵ amalgams with up to 5 per cent. of cadmium are liquid, those with 5–18 per cent. are pasty, and those above that are solid. Amalgams with over 40 per cent. of cadmium appear like that metal. A. Battelli stated that amalgams with mol. proportions Hg : Cd above 5 : 1 are liquid, those with less than 2 : 1 are solid. The solid amalgams are all crystalline. J. Schumann obtained amalgams in fine needle-like crystals. N. A. Puschin said amalgams with up to 63 atomic per cent. of cadmium form polygonal crystals, and those with more cadmium form stellate or tabular crystals. P. I. Bachmetjeff and J. V. Wsharoff showed that the formation of the cadmium amalgams is attended by a contraction. R. Frilley, and E. Maey measured the **specific gravity** and sp. vol. of cadmium amalgams. The latter gave for amalgams with *w* per cent. of cadmium :

<i>w</i>	.	.	.	0	4.1	5.0	15.7	18.3	52.8	100
Sp. gr.	.	.	.	13.552	13.304	13.271	12.933	12.733	10.594	8.631
Sp. vol.	.	.	.	0.07379	0.07517	0.07535	0.07732	0.07853	0.09439	0.1159

R. Frilley assumed that the formation of compounds with Hg : Cd = 12 : 1, 5 : 1, 7 : 2, 5 : 4, 1 : 2, and 1 : 8 is represented by breaks in the sp. gr. curve, and that there is possibly another compound between 1 : 2 and 1 : 4; but E. Maey could draw from his observations no conclusions as to the formation of compounds. T. W. Richards and G. S. Forbes, W. J. Humphreys, and J. Schumann made some observations on the sp. gr. of these amalgams. G. A. Hulett and R. E. de Lury gave for the sp. gr., *S*, of amalgams with *w* grms. of cadmium in 100 grms. of mercury, at 25°, as $S = 13.5340 - 0.0606w$; and a temp. coeff. $-(0.0024 + 0.003w)$. G. Gore found that an amalgam with 20 per cent. of cadmium became dense after repeated melting and solidification. G. Meyer measured the **surface tension** of a cadmium

amalgam against acetic acid; and E. von Schweidler found the coeff. of **viscosity** of amalgams with 2 to 2.8 per cent. of cadmium at 20°, to be 0.01652 to 0.01691 with a temp. coeff. $-0.00364\theta - 0.00360\theta^2$. N. A. Puschin found that the **hardness** of the amalgams of cadmium is greater than those of zinc, lead, bismuth, or tin; L. Guillet, and D. Mazzotto also noted the hardness of these amalgams; and B. Wood stated that an amalgam with equal parts of the two elements is very elastic, and that the **tensile strength** and **malleability** are high; an amalgam with two parts of mercury to one of cadmium is almost as malleable, but its tenacity is less. S. Lussana measured the compressibility of a zinc and cadmium amalgam. C. R. König recommended cadmium amalgam as a stopping for teeth.

J. Schumann measured the **thermal expansion** of some cadmium amalgams between 20° and 145°—*vide supra*. According to R. S. Willows, an evolution of heat occurs in the cooling of cadmium amalgam corresponding with the temp. at which the resistance on a rising temp. coincides with that on a falling temp. The **melting point** or f.p. curve of cadmium amalgams as determined by H. C. Bijl is shown in Fig. 49. The subject has also been studied by N. A. Puschin, E. Jänecke, K. Bornemann, J. Schumann, E. Cohen, D. Mazzotto, R. S. Willows, and H. Iggena. According to E. Cohen, there is a transition point at 23°, and hence he argues that cadmium amalgam is not suited for the standard or normal cell, but W. Jäger and S. Lindeck dissent from this view. C. T. Heycock and F. H. Neville, and G. Tammann measured the **lowering of the freezing point** of mercury by cadmium, and W. Ramsay the **lowering of the vapour pressure**—the computed mol. wt. of the solute agrees with the assumption that monatomic cadmium mols. are present. J. H. Hildebrand and co-workers measured the **vapour pressure** of cadmium amalgams and inferred that a compound HgCd is formed. E. Beckmann and O. Liesche found that by the **boiling point** method, cadmium is present in the monatomic state in the boiling amalgam. R. Schenck measured the ratio of the **thermal conductivity** and the electrical conductivity. J. Marttinen and J. R. Tiihonen determined the **specific heat** of zinc amalgam. J. Regnaud, D. Mazzotto, H. Iggena, and W. Kerp and co-workers have noted the evolution of heat during the formation of cadmium amalgam. In opposition to H. S. Carhart, T. W. Richards and H. L. Frevert have shown that the **heat of dilution** of cadmium amalgam is negative; according to H. C. Bijl, the heat, Q , in cal. developed when a gram-atom of cadmium is dissolved in an amalgam with n per cent. of cadmium at 50°, is:

n	1.99	10.13	17.53	28.51	45.24	65.20	75.01	94.90
Q	509	646	5207	6205	771	204	-223	-16

T. W. Richards and G. S. Forbes found no change of temp. on diluting a 3 per cent. cadmium amalgam. T. W. Richards and G. N. Lewis give 505 Cals. for the **heat of amalgamation** of 1.77 atomic per cent. of cadmium between 0° and 25°; and E. Cohen found 5.436 cal. are needed for separating a gram-atom of cadmium from the 14.3 per cent. amalgam.

The sp. **electrical conductivity**, C , of cadmium amalgams has been measured by C. L. Weber, E. von Schweidler, A. Battelli, and A. Larsen. The latter found for amalgams with w parts of cadmium in 1000 parts of mercury, between 15.9° and 21.3°, and referred to mercury at the same temp.

w	0.163	1.944	6.461	10.38	16.08	24.89	30.81	39.08
C	1.0016	1.0153	1.0496	1.0783	1.1185	1.1785	1.2185	1.2690
$w, 2.75$	θ	.	.	16.8°	44.0°	62.4°	80.4°	
		C	.	1.0292	1.0297	1.0299	1.0301	
$w, 7.42$	θ	.	.	16.0°	46.8°	64.1°	79.3°	
		C	.	1.0568	1.0575	1.0579	1.0583	
$w, 12.27$	θ	.	.	17.1°	35.4°	51.1°	82.9°	
		C	.	1.0918	1.0924	1.0929	1.0941	
$w, 52.48$	θ	.	.	28.2°	39.0°	45.7°	55.3°	
		C	.	1.3491	1.3509	1.3516	1.3533	

K. Bornemann and G. von Rauschenplat have measured the electrical resistance, and the corresponding temp. coeff. of cadmium amalgams. R. S. Willows, and G. Vicentini and C. Cattaneo have made observations on this subject. R. Schenck found the ratio of the thermal and electrical conductivities. A. R. Calvo gave for 0.20 per cent. amalgams, the conductivity $C=0.049436\{1+0.0385(\theta-20)+0.0510(\theta-20)^2\}$; for 0.43 per cent. amalgams, $C=0.049305\{1+0.0390(\theta-20)+0.0510(\theta-20)^2\}$; for 0.69 per cent. amalgams, $C=0.049155\{1+0.0379(\theta-20)+0.0520(\theta-20)^2\}$; for 0.94 per cent. amalgams, $C=0.049020\{1+0.0385(\theta-20)+0.0514(\theta-20)^2\}$; and for 1.50 per cent. amalgams, $C=0.048649\{1+0.0383(\theta-20)\}$. R. S. Willows found that the behaviour of cadmium amalgams was like that of the zinc amalgams: (i) They possess a different resistance, at a given temp., according as they are being heated or cooled, but the resistance is greater with the cooling curve; (ii) the part of the cycle at the higher temp. is reversible; and (iii) the resistance falls when the alloy is allowed to stand at the temp. of the room, but the fall is less than with zinc amalgams, and is completed in three days. The alteration in the resistance is attributed to the slow breaking up of the crystals into more stable forms.

A. Coehn and A. Lotz⁶ found that cadmium amalgam in vacuo is negatively charged against glass. According to J. Regnault, S. Lindeek, and J. M. Gaugain, cadmium amalgam is more electronegative than cadmium. S. Lindeek showed that the **electromotive force** of mercury is markedly changed by small proportions of cadmium, but not so much as with zinc. T. W. Richards and co-workers, and J. H. Hildebrand have studied the e.m.f. of conc. cells with cadmium amalgam. B. Neumann, T. W. Richards and G. N. Lewis, and G. A. Hulett and R. E. de Lury measured the e.m.f. of different cadmium amalgams towards the metal or towards saturated amalgams. V. Rothmund found the potential difference of one per cent. cadmium amalgam towards molar sulphuric acid with 0.01 mol of cadmium sulphate per litre, to be 0.079 volt; the metal itself is negative towards the acid soln. W. Jäger measured the e.m.f. of different cadmium amalgams towards sat. soln. of cadmium sulphate. G. A. Hulett, H. C. Bijl, N. A. Puschin, J. F. Spencer, F. H. Getman, E. Cohen and co-workers, and J. M. Gaugain also measured the e.m.f. of cadmium amalgam against cadmium and a soln. of cadmium sulphate. These cells are of the type $\text{Cd} | \text{CdSO}_4 \cdot 2\frac{2}{3}\text{H}_2\text{O}_{\text{soln.}} | \text{Cd amalgam}$, and the soln. of cadmium sulphate was nearly half sat. at 20°. H. C. Bijl showed that with 8 per cent. amalgam, there is a break in the curve at about 40° representing the variation of e.m.f. with temp. This abrupt change in the temp. coeff. corresponds with a change in the amalgam, for in the vicinity of 40° the heterogeneous 8 per cent. cadmium amalgam changes into a homogeneous liquid phase. The curve BD,

FIG. 51.—Diagrammatic Representation of the e.m.f. Curves of the Different Forms of Cadmium at Different Temperatures.

Fig. 51, represents this change diagrammatically. Between 0° and 40°, the e.m.f. E was found by F. H. Getman, and E. Cohen and fellow-workers to be characteristic of the α -cadmium electrode, and after standing some time $E_a = 0.04862 - 0.000200(\theta - 25)$, curve A, Fig. 51; those with a β -cadmium electrode were found by F. H. Getman to have $E_\beta = 0.04862 - 0.000201(\theta - 25)$, curve B, Fig. 51; and those with γ -cadmium electrode were found by F. H. Getman, and G. A. Hulett, to have $E_\gamma = 0.05047 - 0.0002437(\theta - 25)$, curve C, Fig. 51.

With the β -cadmium electrode, S_2 represents the change in the e.m.f. as the nature of the amalgam at the other electrode changes; S_1 and S_3 respectively denote the corresponding changes when α - and γ -cadmium electrodes are employed—*vide* the allotropes of cadmium. H. S. Taylor

and G. St. J. Perrott studied the e.m.f. of cells with cadmium amalgam and soln. of cadmium chloride or iodide against silver or lead and the corresponding halide. C. Hockin and H. A. Taylor measured the e.m.f. of cadmium amalgam against cadmium and dil. sulphuric acid. Other measurements have been made by C. R. A. Wright, G. Gore, C. H. Wind, F. Krüger, G. Meyer, etc. G. Tammann and W. Jander measured the e.m.f.-conc. curves of zinc, zinc-copper, zinc-silver, zinc-gold, cadmium, cadmium-copper, cadmium-silver, and cadmium-gold amalgams. The **thermoelectric force** of cadmium amalgam has been studied by E. Bouty, W. D. Henderson, and C. L. Weber. L. Arons, O. Lummer and E. Gehrcke, and M. Wolfke used cadmium amalgam in mercury arc-lamps.

The chemical properties of zinc and cadmium amalgams.—A. A. Damour⁷ found an amalgam with one of zinc to six of mercury to be quite stable in dry air; while W. Kerp and co-workers, and A. Bornträger found zinc amalgam to be scarcely affected when exposed to the air. H. Lucas stated that one part of zinc may be detected in 8000 parts of mercury by the black powder which forms on the surface when the mercury is agitated in air. N. A. Puschin stated that cadmium amalgam can be kept in air without oxidation for a long time, and that under a layer of vaseline it does not change appreciably in a year. H. S. Carhart said that cadmium amalgam can be preserved under a soln. of cadmium sulphate. E. de Souza said that zinc or cadmium amalgam retains its mercury at 360°, but not at 440°. V. Merz and W. Weith found that when zinc amalgam is kept in a sulphur vapour-bath for 10–15 hrs., it retains no mercury; if kept 60 hrs. in a mercury vapour-bath, it retains a trace of mercury; and if kept 45 hrs. in a diphenylamine-bath, zinc amalgam retains 2 per cent. of mercury; and after 75 hrs. in the same bath cadmium amalgam retained 0.35 per cent. of mercury, but all the mercury had gone in 100 hrs. After 75 hrs. in an air-bath at 250°–270°, cadmium amalgam retained 3.5 per cent. of mercury. A. A. Damour stated that when heated in air, zinc amalgam decrepitates strongly at a dull red heat, and at a bright red heat, it burns with great brilliancy. G. A. Hulett passed a stream of air through the vapour from zinc amalgam, while this was being distilled, and no zinc was found in the distillate.

According to J. Schumann, zinc amalgam powdered with zinc, decomposes **water** to an appreciable extent, and if air is also present, M. Traube found that some hydrogen peroxide is formed. Dil. **hydrochloric acid** and dil. **sulphuric acid** were found by A. A. Damour, and W. Kerp and co-workers to act but slowly on zinc amalgam. K. Heintz found dil. sulphuric acid has scarcely any action on amalgamated zinc, and, according to C. M. van Deventer, J. F. Daniell, and J. C. d'Almeida this is due to the formation of a protective film of hydrogen over the metal. J. I. Crabtree said that the low solubility of zinc amalgam in dil. acid is due to the high over-voltage of the amalgam which assumes that of the mercury. A. de la Rive showed that the solubility of ordinary zinc in dil. sulphuric acid is due to the formation of small and active voltaic couples on the surface of the metal, and these cause the destruction of the zinc and evolution of hydrogen, apparently on the zinc surface, but really on the surface of the incidental metals. This hypothesis is strengthened by the low solubility of highly purified zinc in the acid. M. Faraday stated:

Amalgamated zinc, even though impure, does not sensibly decompose the water of dil. sulphuric acid, but still has such affinity for the oxygen, that the moment a metal which, like copper or platina, has little or no affinity, touches it in the acid, action ensues, and a powerful and abundant electric current is produced. It is probable that the mercury acts by bringing the surface, in consequence of its fluidity, into one uniform condition, and preventing those differences in character between one spot and another which are necessary for the formation of the minute voltaic circuits. If any difference does exist, at the first moment, with regard to the proportion of zinc and mercury, at one spot on the *surface*, as compared with another, that spot having the least mercury is first acted on, and, by soln. of the zinc, is soon placed in the same condition as the other parts, and the whole plate rendered superficially uniform. One part cannot, therefore, act as a discharger to another;

and hence all the chemical power upon the water at its surface is in that equable condition which, though it tends to produce an electric current through the liquid to another plate of metal which can act as a discharger, presents no irregularities by which any one part, having weaker affinities for oxygen, can act as a discharger to another.

According to G. Vortmann, zinc and cadmium amalgams are readily soluble in dil. **nitric acid**, and A. A. Damour stated that the zinc dissolves first in cold dil. nitric acid, and leaves the mercury unchanged until after the zinc has all dissolved. A. Bornträger stated that zinc amalgam prepared by his process is not attacked by hot **nitric acid**. G. Bischof found that zinc amalgam furnishes hydrogen when immersed in a soln. of **potassium hydroxide**; A. A. Damour, that aq. soln. of **ammonia**, or **ammonium chloridé**, dissolve out the zinc slowly and form water; M. Traube, that when the amalgam is shaken with air and **calcium hydroxide** (milk of lime), calcium peroxide is formed; D. Tommasi, that when zinc amalgam acts on mercuric nitrate in the presence of **potassium chlorate**, the latter is reduced to the chloride; H. N. Morse and W. M. Burton, that a soln. of **potassium iodate** is reduced completely when boiled with zinc amalgam; **potassium bromate** is reduced with greater difficulty; and potassium chlorate, with still greater difficulty; A. Coehn and S. Jahn, that aq. soln. of **carbon dioxide**, and **carbonates** are reduced to formic acid; W. P. Jorissen, that zinc amalgam and dil. sulphuric acid in the presence of **metal sulphides** form hydrogen sulphide; and E. Clemmensen, that **ketones** and **aldehydes** are reduced to hydrocarbons. According to A. A. Damour, when zinc amalgam is immersed in a soln. of a normal **cobalt**, **nickel**, or **copper salt** the metal is precipitated, and it then combines with the mercury; but with a soln. of normal **salts of chromium, uranium, manganese, or iron**, the oxide is precipitated. F. F. Runge found that when zinc amalgam is immersed in an aq. soln. of ferrous chloride, and a crystal of a **nitrate** is placed thereon, a black spot of reduced iron is formed on the amalgam, and this is quickly dissolved by the mercury. No salt other than that of a nitrate was found to give the reaction—e.g. chlorates give no such effect.

§ 44. The Magnesium-Zinc Family of Elements

These elements form a family related in many ways with one another, and with the metals of the alkaline earths. Beryllium and magnesium form a kind of subgroup; zinc, cadmium, and mercury form another subgroup. The metals beryllium and magnesium appear to link the alkaline earths with zinc, cadmium, and mercury. The scheme indicated in the margin is sometimes used to illustrate the idea. There may be a missing member between cadmium, and mercury, since cadmium is much more closely related to zinc than it is to mercury. The vapours of all the elements appear to be composed of monatomic molecules. The chemical relations have been discussed in what precedes; the physical properties of the metals are summarized in Table XII. :—

TABLE XII.—PHYSICAL PROPERTIES OF THE MAGNESIUM-ZINC METALS.

—	Beryllium.	Magnesium.	Zinc.	Cadmium.	Mercury.
At. wt. . . .	9.1	24.32	65.37	112.40	200.0
Sp. gr. . . .	1.64	1.75	6.9-7.2	8.6	13.6
At. vol. . . .	5.5	13.8	9.13	13.0	15.4
M.p.	over 960°	632°	418.2°	320.2°	-38.85°
B.p.	—	1120°	916°	780°	357.3°

The metals are not oxidized so readily as the alkaline earths. The affinity of the metals for oxygen decreases with increasing at. wt. Beryllium does not bear so close a relationship to magnesium, zinc, and cadmium, and, while mercury has a great many similarities, it has many important differences, thus: (1) The salts are all volatile; (2) it does not readily combine with oxygen; (3) its hydroxide is difficult to make; (4) the black sulphide is virtually insoluble in nitric acid; and (5) it forms two chlorides one of which resembles silver chloride. As a matter of fact, the properties of the mercuric salts can scarcely be said to fraternize very closely with the salts of any other metal.

The carbonates of these elements break up when heated into carbon dioxide, and a residual oxide, and, with the exception of magnesia, the oxides are but sparingly soluble in water. Magnesium oxide is white; zinc oxide is white when cold, yellow when hot; cadmium oxide is yellow when cold; and mercuric oxide is red or yellow. The oxides and hydroxides are soluble in soln. of ammonium salts. The basic character of the hydroxides decreases with increasing at. wt. The hydroxides are not made by direct union of the oxide with water, and the water is easily expelled from the hydroxides by heat. This is not the case with the hydroxides of the alkaline earths. The sulphates are soluble and zinc and magnesium sulphates are isomorphous; the sulphates are all less stable than those of the alkaline earths, and their stability decreases with increasing at. wt. The sulphates all combine with potassium sulphate—*e.g.* $\text{ZnSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$. The chlorides are all volatile deliquescent solids; zinc and magnesium chlorides are readily hydrolyzed in aq. soln., and form basic salts when the soln. are evaporated to dryness. This is not the case with cadmium and mercuric chlorides. The two latter readily combine with ammonia to form complex salts, and cadmium, like mercury, forms a lower oxide and chloride; the iodides of these two elements are isomorphous. The halides become less stable on passing from beryllium to mercury. The sulphides increase in stability and are less soluble as the mol. wt. increases. The sulphides of the first two elements are not formed in the presence of water; zinc sulphide is stable in aq. and slightly acidic soln.; cadmium sulphide is dissolved by conc. but not by dil. acids; whereas mercuric sulphide is scarcely attacked, even by boiling nitric acid.
